Favorable Action of Nitrite of Amyl on Hysterical Manifestations.—Hirtz and Loust communicate two observations in which the various hysterical phenomena have disappeared under the influence of the vasodilator action of amyl nitrite. Hirtz recalls a former paper in which he described a certain malady under the term "angiospasmodic malady." This affection appears under the form of peripheral angiospasm and precedes arteriosclerosis. It can show itself also by visceral angiospasm, and can constitute, according to the localization in the cerebrospinal system, all of the phenomena of hysteria and of hystero-neurasthenia It may end by localization in the vessels of the kidney, in albuminuria. In the stomach angiospasm may create ulcerations with hæmatemesis. On this theory of angiospasm, the favorable action of amylnitrite may be explained, since this action is vasodilator.—*La Bulletin Médical,* April 4, 1903.

Ureteral Calculus of 44 Grams; Transperitoneal Ureterolithotomy; Recovery.—C. Jacobs observed this patient. She was forty-four years of age and a multipara. She complained of painful crises, clearly localized in the left pelvis. Every crisis was followed by emissions of purulent urine. After the crisis passed, the urine again became limpid. She had suffered pain in the left pelvis since the age of ten years. The urine had never been bloody, and there had rarely been fever. Examination revealed, very high in the left pelvis, at the level of the ovary, a tumor about the size of a mandarin, non-adherent, regular, hard, slightly sensitive. Laparotomy was decided upon. The genital organs were found to be normal. The rectum was deviated toward the middle of the pelvis. Under the adnexa and covered by the peritoneum of the broad ligament, was the tumor. It was elongated, hard, regular, movable. Ureteral calculus was diagnosticated. It was removed and no other calculi were found. The kidney was normal in size. The calculus weighed 44 grams. The ureteral wound was closed by fine silk sutures. For two days the urine was bloody, but then became clear. There were no other abnormal symptoms. Three weeks after the operation the patient left the hospital in excellent condition.—*Annales de Gynécologie et d'Obstetrique*, February, 1903.

Suppurative Cholecystitis Simulating the Vomiting of Pregnancy and Terminated by the Syndrome of Cerebrospinal Meningitis.—M. P. Le Gendre reports the case of a woman aged thirty-four years. She came complaining of vomiting. She had not menstruated for two months and presented the nervous symptoms of beginning pregnancy Pathological antecedents were nil. Aside from slight anteflexion of the uterus, there was nothing abnormal about the viscera. Vomiting was not painful. It ceased after lavage of the stomach. Suggestion probably was influential in this. Again, vomiting began and was incessant. It was now spontaneous and bilious, accompanied by anorexia. The skin was jaundiced. The urine did not contain biliary pigment, but a little albumin. The temperature rose, and the pulse; there developed in a few days constipation, incontinence of urine, irregularity of the pupils, and Kœnig's sign, with numerous lymphocytes in the cerebrospinal fluid from lumbar puncture. Death came in coma six days after the beginning of fever. At autopsy a stone, large as a nut, was found at the entrance to the cystic canal, and a number of smaller stones. Besides the purulent cholecystitis, there was diffuse congestion of the nervous centers.—*Annales de Gyéncologie et d'Obstétrique,* April, 1903.

A Prerenal Abdominal Cyst, Probably Hydatid, Simulating a Voluminous Hydronephrosis of the Right Side; Extirpation; Recovery.—E. Vincent gives an account of this case. The patient was a woman of fifty-five years. The illness began like a gastrointestinal infection. Later it simulated typhoid fever. Treatment consisted in medicaments for the disinfection of the digestive tube. On the thirty-third day of the supposed fever, there occurred a crisis characterized by chills, rise in temperature, vomiting, pain in the right side, and meteorism. Examination of the abdomen revealed a hard tumor, occupying the right iliac fossa or rather the right of the abdomen. The writer was called and first thought both of hydatic cyst of the liver and of the kidney. The internal genitals were not involved. After further study the diagnosis of hydronephrosis seemed most rational. The character of the urine supported this decision. Operation, however, revealed a cyst, the contents of which were like that of an old hydatid cyst. Whatever the seat of this cyst may have been, the mesocolon, or the right border of the great omentum, nevertheless, it must be admitted that abdominal cysts lodged in front of the kidney can be mistaken for hydronephrosis, and that even careful study of the case will not always prevent error in the diagnosis.—*Lyon Médical,* March 15, 1903.

Annals of Surgery, March, 1903.

Blank Cartridge Wound Infected with Tetanus Bacilli; Prompt Excision; No Tetanus.—J. B. Bain reports the case of a girl of thirteen years who was shot in the palm of the right hand with a blank cartridge. Thorough excision was performed and healing occurred without incident. All the tissue removed at operation, together with the particles of wadding and powder grains found in the wound, were placed in a culture tube of coagulated blood serum and sent to the laboratory to be examined for tetanus bacilli. After three days in the incubator, a considerable growth of bacteria had occurred in the tube, examination of which showed numerous micrococci and bacilli. Some of the bacilli had spherical spores situated at one end, and were identical with tetanus bacilli in appearance. These were isolated in pure culture by means of anaerobic plate cultures and were found to be true tetanus bacilli. The author claims that this is the first case in which tetanus bacilli have been isolated from a wound without the occurrence of tetanus symptoms in the patient.

Sixty Cases of Actinomycosis.—R. Von Baracz gives a general description of this disease as seen in Galicia. Concerning treatment, he says that as the disease generally produces a hard wall around the softened area and this wall hinders the extension of the process, he has endeavored to produce such a wall which consists of connective tissue, by the hypodermic injection of irritants like tincture of iodine and 20-per-cent. solutions of silver nitrate. In this way he was able to cure his last nine cases without operation. He states that silver in this strength not only produces a boundary wall but also kills the fungus. As to animal inoculation, he tried it in mice, pigeons, hens, dogs, and rabbits. In mice, pigeons, and hens the fresh grains containing the fungus were introduced under the skin, but they disappeared entirely after some weeks. In dogs the grains were inoculated into the peritoneum, and they also disappeared. Only in a few rabbits the inoculation resulted in tumor-formation after six weeks. The tumors were examined microscopically, and proved to be only irritative changes, as produced by other foreign bodies. In the specimens are seen the formation of epithelioid cells surrounded by lymphoids, a view shown in encapsulation of foreign bodies.

Knife-blade Removed from Lung.—In the case of J. F. Baldwin a knife-blade was located by the *x*-ray in the lung of a man who had been stabbed three months before coming under observation. The external wound had healed, but an intrathoracic condition had developed resembling the consolidation of phthisis with distinct sepsis. The operation for the removal of the blade is thus described: About an inch of the overlying rib was resected, the incision being made in the axillary line just below the scar left by the wound of entrance. It was expected that adhesions would be found at this point, so that the pleural cavity should not be opened, and this proved to be the case. A finger was pushed into the lung substance without difficulty, and thus hemorrhage was obviated. The blade was encountered at a depth of about a finger's length, and forceps being introduced along the finger the blade was extracted. Drainage was introduced, and for several days there was considerable purulent discharge from the cavity in which the blade had been lying, this discharge being of a most offensive nature. It lasted, however, but a short time, and the patient was able to return home, with the wound healed and in greatly improved health, sixteen days after the operation. His recovery was prompt and complete.

Acute Yellow Atrophy of the Liver as a Sequela of Appendectomy.—The patient of Max Ballin was a young

brass-worker of twenty years operated upon for an acute appendicitis. The appendix, cæcum, and omentum were quite inflamed and swollen. The first three days after the operation everything looked favorable except a slight icterus. Then in the fourth night serious delirium developed, very violent spasm set in, only to be interrupted by a deep comatose condition. At the same time deep icterus existed, hemorrhagic masses were vomited, bile, albumin, casts, leucin, and tyrosin appeared in the urine, the liver dulness was much diminished. This serious condition lasted five days, to yield finally to a slow improvement. According to the author, there can be no doubt but that he had to deal with a case of acute yellow atrophy of the liver after an appendectomy under chloroform. All the typical symptoms were present, viz., icterus, delirium, spasms, coma, fever, leucin, and tyrosin in the urine. Even the small liver-dulness could be percussed. He thinks that everyone would agree with his diagnosis if he could add to the record of the case an autopsy report. Commenting on the possibility of a mistaken diagnosis, he says there are some undoubted recoveries from this disease, though the mortality is about 95 per cent. He could find only nine cases following operation. Of these a tabulated analysis is given.

The Treatment of Infantile Spastic Paralysis.—Robert Jones groups cases as follows: (1) Infantile hemiplegia; (2) Cerebral diplegia, and (3) Spastic paraplegia. In the first group the following are from the point of treatment the conditions: The upper limb is more severely affected than the lower, the lesion of the upper limb is more permanent, the power of dorsi-flexion of the hand with simultaneous extension of the fingers is lost, movements are performed without precision, spasmodically and slowly. The power of adduction of the thumb is often lost. The disabilities of the lower limb are generally: contraction of the knee, extension of the foot, internal rotation of the femur with adduction and general rigidity.

In the second group we may divide the cases into (1) those with and without mental complications; (2) those with complete and partial disability of hands; (3) the same condition in the feet, and (4) cases complicated by athetotic movements. The third group comprises those cases characterized by the confinement of the spasms to the limbs, Little's disease or spastic paraplegia. The pathological conditions in all three groups are the same in kind, and the symptoms are due to retardation of growth resulting generally from embolism or thrombosis, together with changes in the cord. The general principles of treatment which cannot be detailed here consist in keeping the various extremities in proper position. At times tenotomy is necessary. Tendon transplantation is in other cases more serviceable. Succeeding operative measures are various movements which must be left to the ingenuity of the surgeon. They should be practised slowly and without excitement; should be made interesting to the child; should consist mainly of those opposed to the direction of the deformity, and those presenting the greatest difficulty should be the ones chiefly practised.

Archives of Pediatrics, March, 1903.

Amygdalitis Followed by Appendicitis, Nephritis, and Endocarditis.—E. W. Mitchell reports the case of a child who suffered from the above-named affections in rapid sequence. Death appeared to be imminent, but an infusion of normal salt-solution after not very free bleeding was followed by recovery, which has become complete. The rapid sequence of nephritis, endocarditis, and pyelitis, all plainly of septic origin, could hardly be otherwise explained than by a generalized infection. Whether this general infection was from absorption from the appendix, or whether the infections of the appendix and of the blood were both from some common source, as the tonsils, are questions which we are not, in the present state of knowledge, able to answer positively. In this case the probabilities are largely in favor of the latter view.

Clinical Observations on Circulatory Failure in Acute Infectious Disease.—Augustus Caillé says that saline infusion and hypodermoclysis may be relied upon to stimulate promptly and safely in circulatory failure. The action of both is more prompt than that of drugs and apparently increases the effect of drugs given hypodermically. In the treatment of septic cases, infusion should be reserved for those in which there has been a decided loss of body fluids, as in severe choleraic or typhoid diarrhœa. Enteroclysis properly carried out with Kemp's flexible double current catheter (fifteen minutes' flow of water at 110°) appears to be an absolutely safe method of combating circulatory failure in septic conditions. It stimulates kidney secretion and thereby promotes the elimination of poisons; it induces intestinal absorption of water whenever the body craves water. It has a certain effect in reducing temperature. It appears to be indicated as a routine treatment in all septic conditions, even if the kidneys be not involved. In severe anæmia enteroclysis is followed by an actual improvement of the blood mixture independent of the administration of drugs.

The American Journal of the Medical Sciences, March, 1903.

Aphasia in Acute Disease, with Report of a Case Complicating Smallpox.—Charles J. Aldrich reports the case of a boy of seven years who had an attack of smallpox. There was at first no rash upon the body, nor did thorough physical examination reveal other signs of disease. The trouble was thought to be gastrointestinal. The next day the child went into violent convulsions for about an hour. After they subsided the child was stuporous. He paid no attention to anything whatever. On the morning of the fourth day the characteristic eruption of smallpox appeared, the temperature fell, and the child became conscious. But he was completely aphasic, and for over three months he did not speak a single word. In the course of six months he was speaking fluently again, but he had to be retaught speech. His aphasia could not be properly classified, but it certainly, was not motor.

Upon the Association of Epilepsy and Heart Disease.—T. L. Chadbourne concludes that in none of his cases has he been able to show satisfactorily that there was any direct connection between the vascular lesions and the epilepsy. There was, as a rule, a clear history of acute infectious disease, followed by heart lesions, several times with symptoms on the part of the heart before the onset of the attacks, and, finally, by epileptic seizures. The writer thinks it more than doubtful if the occurrence of heart lesions in epilepsy is anything more than a coincidence. At least the verdict of "not proven" must hold at present. There is no satisfactory direct proof that cardiovascular disease is a cause of epilepsy; therefore, the demonstration of their connection must rest upon methods of exclusion: Stintzing's postulates are: "(1) The heart disease must precede the epilepsy. (2) Other causes must be excluded. (3) The coincidence must be frequent. (4) Improvement in the heart disease must improve the epilepsy." The coincidence of the two diseases is not very frequent. Upon the whole these postulates are not fulfilled.

The Clinical Value of Blood-pressure Determined as a Guide to Stimulation in Sick Children.—Henry Wireman Cook describes the principle of the instrument used in these observations as a continuous system of air, so arranged that equal pressure can be transmitted from a rubber belt held by the operator to a band placed around an arm or leg of the patient, and at the same time connecting with a mercury manometer which registers the pressure in millimeters. In this way the operator can, by a valvular arrangement in the bulb, gradually increase the pressure throughout the air system, raising simultaneously the mercury column and constricting the arm or leg. Keeping a finger on the pulse of the patient's limb, on which the constricting band is placed and distal to the band, the operator can read off on the manometer scale the height of the mercury column at the moment the pulse is lost. Just at that moment such a pressure is being applied to the artery under the band that approximates the systolic pressure in the arterial system. The instrument is very easy of application. The cases stimulated included marasmus, pneumonia, rachitis, pertussis, tuberculosis, and summer diarrhœa. The writer concludes by insisting that it is not meant that blood-pressure observations, in any form of treatment, should take the place of other signs and symptoms, but merely that an accurate estimation of arterial tension furnishes an additional and valuable aid to stimulant therapy. A certain blood-pressure reading is no absolute indication of a patient's condition, but the writer believes that variations in blood-pressure numerically determined constitute the best single guide to the intelligent administration of stimulants.

Indications for Operation in the Hemorrhages of Gastric Ulcer.—Albert Mathien and J.-Ch. Roux consider first acute hemorrhage that does not yield to medical treatment. In these cases operation is justified only when the surgeon can directly arrest the hemorrhage by excision of the ulcer ligature of the artery or any proceeding whatever of hæmostasis. In acute gastric hemorrhage, operation is rarely indicated. As to chronic hemorrhages less abundant but continuous, operative intervention gives in this variety the best results. Gastroenterostomy is the operation indicated in this form, as well as in the repeated acute hemorrhages, when there is an ulcer of the pylorus causing stenosis.—*Gazette des Hôpitaux, Civils et Militaires*, April 23, 1903.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-fourth Annual Meeting, Held at New Orleans, La., on May 5–9, 1903.

GENERAL SESSION, THIRD DAY, THURSDAY, MAY 7.

Oration on State Medicine.—Dr. William H. Welch of Baltimore delivered this oration. He said that fourteen years ago he had had the honor of delivering the oration on State Medicine. Since that time we had not come into possession of new methods having the novel and revolutionary character of those initiated by Koch. However, many new vistas of knowledge had been disclosed by the investigations on antitoxin and immunity; the study of the complex toxins, including snake venom; the discovery of the specific germ of chancroid, of influenza, of bubonic plague and of acute dysentery; the establishment of the micrococcus intracellularis as the infectious agent in cerebrospinal meningitis; the recognition of blastomycetic dermatitis, the demonstration of the agency of the mosquito in the transmission of malaria and of yellow fever, and the recent significant addition to our knowledge of the specific causation of hay fever and of smallpox. To this incomplete list could be added a host of minor discoveries. Surely this record of scientific discovery and of practical achievement during the recent years gave every encouragement to expect continued and increasing advances in knowledge along similar and new lines in the near future!

No Conflict between Epidemiology and Bacteriology.—Any disease caused by a pathogenic organism was now considered to be an infectious disease without regard to the mode of propagation of the disease. It was a narrow conception to suppose that the knowledge of the properties of infectious agents was acquired only in the laboratory. Medical bacteriology should be the handmaid of epidemiology and of clinical medicine, and he would suggest that we did not apply, to the extent which we should, knowledge derived from these sources. It was certain there could be no real contradiction between the facts of epidemiology and clinical medicine, on the one hand, and those of bacteriology on the other, and any such apparent contradiction was the result either of our ignorance or of a one-sided consideration of the subject. The science of epidemiology was a much older and broader one than that of bacteriology. Half a dozen years ago the belief generally prevailed that the germ of malaria was directly transported on the air, and that a malarial patient was incapable of infecting a locality. Most of us now saw that the discovery of the agency of the mosquito in the development and transportation of the malarial parasite afforded a complete explanation of the previously well-established fact relating to the origin of this disease, and had disclosed wholly new points of view of far-reaching scientific and practical significance.

Ultra-microscopic Organisms.—While the presumed parasite of rabies had never been demonstrated, we had considerable information regarding the sphere and nature of its action. On this information was based the very successful preventive treatment of hydrophobia devised by the brilliant Pasteur. We had an abiding faith that all infectious diseases were caused by microorganisms; hence, every new discovery of this kind was to be welcomed, especially one of such significance as that recently announced by Dr. W. T. Councilman. As this was the first complete demonstration of the specific germ of one of the contagious exanthematous fevers it was to be hoped that it would lead to the disclosure of the secrets of other members of this group. The evidence pointing to the possible existence of germs so small as to be entirely beyond the reach of the most powerful microscopes was certainly somewhat discouraging. It was based on the fact that certain viruses could pass through the pores of a Chamberland porcelain filter. Reasoning from analogy, there was good ground for believing that the virus thus passing through was a living organism; any other conclusion regarding the nature of this class of infectious viruses would necessitate almost revolutionary changes in our conception of certain infectious diseases, but it was only fair to recognize the importance and the obscurity of the problems raised by the discovery of these viruses, and not to forget the danger of analogical reasoning in biology.

Serumtherapy.—During the past decade there had been no more fascinating studies than those with regard to immunity. In late years these studies had tended more and more into paths difficult for those not directly concerned to follow, and which seem for the present to lie rather remote from the paths of practical and curative medicine. The high hopes that the discovery of the diphtheria and the tetanus antitoxic serums would soon be followed by the discovery of similar curative serums for other infectious diseases, had been disappointed. The fact was not yet sufficiently familiar to practitioners that the various other healing serums, such as the antistreptococcus, the antipneumonia, antityphoid and antiplague serums, did not belong to the class of antitoxic serums, and that they depended for their action upon principles which at present interposed serious obstacles to their successful employment in the treatment of human diseases. The prophylactic and curative value of diphtheria antitoxin was now so firmly established that the main question relating to it in State medicine had to do with effective methods of controlling its manufacture and sale. The antitoxic treatment of tetanus had not yielded results at all comparable with those obtained by the specific treatment of diphtheria, and the reason was not the inferior quality of the tetanus antitoxin, but our inability to recognize the disease and so begin the treatment before a fatal quantity of toxin had entered into combination with the constituents of the nerve cells. There was, however, a field of application for this serum not yet sufficiently appreciated, *i. e.* its prophylactic use. It was a far easier matter to protect against the outbreak of a disease by the preliminary administration of its specific serum than to cure the disease after symptoms had appeared. There was much evidence from veterinary practice, and some from human medicine, in favor of this prophylactic use of tetanus antitoxin.

Rabies.—Of the application of the principle of active immunization to preventive medicine there were several examples, but the two most striking and important ones were smallpox and rabies. We knew that in vaccination and revaccination we had an effectual weapon for the extermination of smallpox, and that no more baseless and pernicious error had been promulgated than that of the antivaccinationists. The speaker said that he had long held that rabies, while not a frequent disease, was more common in this country than generally supposed, and that it merited serious consideration. It was curious that there should have prevailed so much skepticism regarding the occurrence, and even the very existence of this disease. This attitude was largely attributable to a failure to remember that rabies was primarily and largely a disease of the lower animals, and was only exceptionally transmitted by them to man. Dr. Salmon had shown, by convincing figures, that the disease was not particularly uncommon in dogs, horses, cattle, and cats. The disease itself was as definite as typhoid fever, and as susceptible of positive diagnosis by experimental test. The danger to man cou'd be reduced to a minimum in most localities by a proper enforcement of dog-muzzling laws. With regard to the efficacy of the Pasteur treatment of rabies, he felt there could be no doubt in the mind of any one who had carefully studied the records of the Pasteur Institute in France. Thus, among the untreated cases the mortality from rabies was 80 per cent., whereas among those treated

sufficiently early by the preventive Pasteur method the mortality was less than 1 per cent.

Typhoid Fever.—Typhoid fever must still maintain a prominent position in any consideration of State medicine, but only two or three points would be emphasized at this time. The speaker then raised the question as to whether our prophylactic measures took into account the fact that the original infectious agent was always a typhoid-fever patient. In crowded tenements and under insanitary conditions, this direct mode of transmission from one patient to anotherprobably occurred more frequently than would appear from the statements made in the textbooks. Ordinarily, however, the route before reaching the second person was so long and so circuitous that it could not be readily followed. If we could secure the total destruction, or prevent the escape of the living typhoid bacilli derived from this source, there was good reason for believing that typhoid fever would disappear. Certainly much more could be done in this direction than was done. The efficacy of proper sanitary measures for the disposal of sewage and the protection of the drinking water from contamination with typhoid fever were so generally recognized that town and municipal authorities, who were indifferent to such measures, took upon themselves a grave responsibility. It was remarkable that this country should have lagged so far behind Germany, England, and France in the application of sand filtration to the purification of the drinking water of our cities. We should not forget that typhoid fever was a disease of the rural districts rather than of cities.

The Acute Dysenteries.—The etiology of acute dysentery had many points in common with that of typhoid fever. We now know that the acute dysenteries in this country were produced in large part by the dysentery bacillus discovered by Shiga in Japan. It was highly probable that this bacillus had much the same haunts and distribution in nature, as the typhoid bacillus. Of far-reaching significance was the finding by Duval and Bassett of Baltimore of the dysentery bacillus in a series of cases of the summer diarrhœa of infants. It was now recognized that these two main types were not known to correspond to anatomically or clinically distinct forms of dysentery, or, indeed, to differ essentially from each other in their action. The coming summer would probably see a thorough trial of the anti-dysenteric serum prepared by Dr. S. Flexner. That these discoveries would prove to be of much importance to preventive medicine could scarcely be doubted.

Tuberculosis.—The most stupendous task ever attempted by modern preventive medicine was the crusade against tuberculosis inaugurated by certain dauntless spirits in the medical profession, and it required, and should receive, the hearty coöperation of the people generally, as well as of the profession. The sanitary problems of tuberculosis related partly to the welfare of the consumptive patient, and partly to the protection of the community from infection. Among the most important measures was the establishment of sanatoria for the treatment of early cases and of hospitals for advanced and hopeless cases. Essential as these institutions were, the main emphasis should be laid not upon their value in the prophylaxis of this disease, but upon their importance to the welfare of the patient. There were various sources of infection, but all of them sunk into insignificance in comparison to the importance of the dried and pulverized sputa of the tuberculous patient. However, the danger from "drop infection" should be remembered, particularly by physicians, nurses, and attendants. The danger from the milk of tuberculous cows he believed to be a real one, though not so great as was formerly believed. Among the various public sanitary measures a prominent place had very properly been given to the enactment of anti-spitting ordinances education of the public was another important part of the campaign in which the coöperation of charity organization societies and other lay organizations could be of inestimable assistance. A system of registration of tuberculous cases he considered to be essential to the success of this antituberculous crusade, and the success of this measure in New York City should disarm all adverse criticism.

Malaria and Yellow Fever.—Among the discoveries of recent years, none surpass in interest those concerning the rôle of insects in the transmission of pathogenic organisms. A very important contribution to our knowledge of this subject had been made by a commission composed of Reed, Vaughn, and Shakespeare. The labors of this commission in the inspection of camp life during the late Spanish-American war were most painstaking and thorough, and led to important results. Nanson's demonstration of the agency of the mosquito in the transmission of pityriasis opened the way for later studies along this line but the subsequent researches regarding malaria and yellow fever really originated in the investigation of Theobald Smith into the nature of Texas fever. It had been practically proved that primary malarial infection was due solely to the bite of infected mosquitos of the genus anopheles. It should be borne in mind that a person once infected might harbor malarial parasites in a latent condition in his body for months or even years, and might suffer from relapses by going to a non-malarial region. We were justified in asserting that the extermination of this disease from a locality was possible, however difficult of accomplishment in most cases this must be. The main points in the prophylaxis of malaria were: (1) A systematic search, by means of blood examinations, for malarial parasites in the inhabitants of a certain locality, both the well and the sick; (2) the protection of persons against the bites of infected mosquitos by the use of mosquito screens; (3) the extermination of the mosquitos by drainage of pools and other methods.

Tribute to the Late Major Reed.—Referring to the work on yellow fever, Dr. Welch said that Major Reed be looked upon as one of the greatest benefactors of his race, and one of the greatest adornments of American medicine. The results accomplished in determining the mode of spread of yellow fever through the agency of the mosquito had been proved to be of the utmost benefit to mankind. It had resulted in the extermination of this disease from Cuba, and the number of lives saved and to be saved outnumbered vastly those lost in the war. The name of Major Reed should ever be held in honorable memory by the people of this country.

GENERAL SESSION, FOURTH DAY, FRIDAY, MAY 8.

Report of the House of Delegates.—At the last general meeting of the association, according to order, a summary of the proceedings of the house of delegates was given

Report of the Board of Trustees.—Dr. T. J. Happel of Tennessee, Chairman, presented this report. This showed that the total membership of the association was 12,553, and that during 1902, there had been a gain in New York State of 317 members. A comparison with the report presented at the Denver meeting, five years ago, showed that the present membership was almost twice as great as at that time.

With regard to the question of a national incorporation, about which there had been so much agitation recently, the report stated that it had been given earnest and exhaustive consideration, both by the trustees and by their legal counsel, and a lengthy opinion from the latter was submitted. Briefly, the opinion states: (1) That the constitution and by-laws adopted at St. Paul had no binding force at all until they were readopted in Illinois, but the action had at Saratoga, and readopted in Chicago, was binding, and the charter and by-laws under which the association was now acting were legal, since they were readopted in Illinois, where the association was incorporated; (2) that a national incorporation was an impossi-

bility, because Congress had no power to create a national incorporation for the purposes mentioned in the charter of the association and to give such association the power to do business in any of the States or Territories of the Union, and (3) that while Congress had the power to create such a corporation, and, in fact, had done so in the case of the American Social Science Association, it only allowed of the transaction of business in the District of Columbia, so that the only difference over the present situation would be that the business done at our annual meetings would have to be ratified in the District of Columbia instead of, as at present, in the State of Illinois —manifestly no advantage. So much general interest was taken in this subject, that the portion of the trustees' report dealing with the question of national incorporation was referred to a special committee for further consideration.

Report of the Committee on Prophylaxis of Venereal Diseases.—The committee, consisting of Henry D. Holton, Chairman; Ludwig Weiss, George M. Kober, W. H. Sanders, L. Duncan Bulkley, and Louis E. Schmidt, presented its report. Emphasis was laid upon the fact that it had confined its studies only to the question of whether the enormous spread of venereal diseases could be inhibited by a systematized action emanating from the medical profession, and that the conclusion had been reached that, no matter what the point of view, the profession would have the decisive word in the premises. The committee had felt keenly the utter want of statistics from boards of health. Twenty States and twenty large cities had replied to a circular letter of inquiry, and there evinced a growing interest in the subject and a readiness for coöperation. The report then quoted statistics from various sources, showing convincingly that venereal diseases stood next to tuberculosis and alcoholism in importance, 15 to 20 per cent. of adult males being infected with syphilis and about 80 per cent. having had gonorrhœa. Moreover, 80 per cent. of all deaths from pelvic disease in women were due to gonorrhœa; 20 per cent. of all blindness was due to gonorrhœal infection of the newborn; 50 per cent. of all involuntary childless marriages were caused by gonorrhœa of the female generative organs, and the original source of the gonorrhœal infection was traceable in about 70 per cent. of the cases to prostitutes. According to recent government statistics, it had been computed that in Berlin, among men marrying after their thirtieth year, every one had suffered from gonorrhœa twice, and every fifth man had been infected with syphilis. It was a most significant fact that, in the northern countries of Europe in which generous hospital facilities had been placed within the reach of all venereal patients, these diseases had markedly diminished. London, in order to cope successfully with venereal diseases, should have for its 6,300,000 inhabitants about 2,500 beds for such patients, and Greater New York, with its 3,500,000 people, should have, at least, 1,500 beds. In conclusion, the committee recommended that a national congress for the prophylaxis of venereal diseases should be convened, under the auspices of the American Medical Association, and that the delegates from each State, or special committees for this purpose, be authorized to organize such a movement in their respective State and district societies and send delegates to such congress. This recommendation was favorably received and the committee was continued.

Adoption of a New Code of Ethics.—The most important business transacted by the house of delegates was the adoption of a new and revised code of ethics, although the word "code" has been eliminated in these "principles of ethics." When the committee on revision, consisting of Drs. E. Eliot Harris, Joseph D. Bryant, William H. Welch, T. J. Happel, and J. N. McCormack, first submitted its report, the matter was referred to an enlarged committee representing all the States.

The following is the full text of the report:

"Principles of Medical Ethics of the American Medical Association."

The American Medical Association promulgates as a suggestive and advisory document the following:

CHAPTER I.—THE DUTIES OF PHYSICIANS TO THEIR PATIENTS.

"Section 1. Physicians should not only be ever ready to obey the calls of the sick and the injured, but should be mindful of the high character of their mission and of the responsibilities they must incur in the discharge of momentous duties. In their ministrations they should never forget that the comfort, the health, and the lives of those entrusted to their care depend on skill, attention, and fidelity. In deportment they should unite tenderness, cheerfulness, and firmness, and thus inspire all sufferers with gratitude, respect, and confidence. These observances are the more sacred because, generally, the only tribunal to adjudge penalties for unkindness, carelessness, or neglect is their own conscience.

"Sec. 2. Every patient committed to the charge of a physician should be treated with attention and humanity, and reasonable indulgence should be granted to the caprices of the sick. Secrecy and delicacy should be strictly observed; and the familiar and confidential intercourse to which physicians are admitted, in their professional visits, should be guarded with the most scrupulous fidelity and honor.

"Sec. 3. The obligation of secrecy extends beyond the period of professioual services; none of the privacies of individual or domestic life, no infirmity of disposition or flaw of character observed during medical attendance should ever be divulged by physicians. The force of the obligation of secrecy is so great that physicians have been protected in its observance by courts of justice.

"Sec. 4. Frequent visits to the sick are often requisite, since they enable the physician to arrive at a more perfect knowledge of the disease, and to meet promptly every change which may occur. Unnecessary visits are to be avoided, as they give undue anxiety to the patient; but to secure the patient against irritating suspense and disappointment the regular and periodical visits of the physician should be made as nearly as possible at the hour when they may be reasonably expected by the patient.

"Sec. 5. Ordinarily, the physician should not be forward to make gloomy prognostications, but should not fail, on proper occasions, to give timely notice of dangerous manifestations to the friends of the patient; and even to the patient, if absolutely necessary. This notice, however, is at times so peculiarly alarming when given by the physician, that its deliverance may often be preferably assigned to another person of good judgment.

"Sec. 6. The physician should be a minister of hope and comfort to the sick, since life may be lengthened or shortened not only by the acts but by the words or manner of the physician, whose solemn duty is to avoid all utterances and actions having a tendency to discourage and depress the patient.

"Sec. 7. The medical attendant ought not to abandon a patient because deemed incurable; for, continued attention may be highly useful to the sufferer, and comforting to the relatives, even in the last period of the fatal malady, by alleviating pain and by soothing mental anguish.

"Sec. 8. The opportunity which a physician has of promoting and strengthening the good resolutions of patients suffering under the consequences of evil conduct ought never to be neglected. Good counsels, or even remonstrances, will give satisfaction, not offense, if they be tactfully proffered and evince a genuine love of virtue, accompanied by a sincere interest in the welfare of the person to whom they are addressed."

CHAPTER II.—THE DUTIES OF PHYSICIANS TO EACH OTHER AND TO THE PROFESSION AT LARGE.

"Article 1. Duties for the support of professional character.

"Section 1. Every one on entering the profession and

thereby becoming entitled to full professional fellowship, incurs an obligation to uphold its dignity and honor, to exalt its standing and to extend the bounds of its usefulness It is inconsistent with the principles of medical science and it is incompatible with honorable standing in the profession for physicians to designate their practice as based upon an exclusive dogma or a sectarian system of medicine.

"Sec. 2. The physician should observe strictly such laws as are instituted for the government of the members of the profession; should honor the fraternity as a body; should endeavor to promote the science and art of medicine and should entertain a due respect for those seniors who, by their labors, have contributed to its advancement.

"Sec. 3. It is the duty of every physician to identify himself with the organized community in which he resides. Where local or county medical societies do not exist, physicians, recognized as such by law and known to each other to possess good moral and professional character, should assemble in convention and effect an organization, and thereafter any physician, recognized as such by law, residing within the county and possessing a good personal and professional character, whatever may be his individual views on any question connected with the science of medicine, ought, on application, to be considered eligible to membership.

"All county medical societies thus organized ought to place themselves in affiliation with their respective State association, and the State associations, in turn, with the American Medical Association.

"Sec. 4. Physicians should be active in their support of their respective county societies, which constitute the chief element of strength in the organization of the profession. The county societies should be utilized for the cultivation of fellowship, for the exchange of professional experiences, for advancement of medical knowledge, by means of papers, essays and addresses, and by bringing within their midst, when practicable, laboratory demonstrations of the latest developments of scientific methods. They should enact and enforce resolutions and ordinances touching all ethical questions of local importance, and each county society should discipline its own members, always, of course, subject to appeal to its respective State association. County societies should, furthermore, secure concert of action and should coöperate with their respective State associations on all matters of pending legislation touching the interests of the profession and of the public and common interests of both.

"Sec. 5. There is no profession from the members of which greater purity of character and a higher standard of moral excellence are required than the medical; and to attain such eminence is a duty every physician owes alike to the profession and to patients. It is due to the patients, as without it their respect and confidence can not be commanded; and to the profession because no scientific attainments can compensate for the want of correct moral principles.

"Sec. 6. It is incumbent on physicians to be temperate in all things, for the practice of medicine requires the unremitting exercise of a clear and vigorous understanding; and in emergencies—for which no physician should be unprepared—a steady hand, an acute eye and an unclouded mind are essential to the welfare, and even to the life, of a human being.

"Sec. 7. It is incompatible with honorable standing in the profession to resort to public advertisements or private cards inviting the attention of persons affected with particular diseases; to promise radical cures; to publish cases or operations in the daily prints, or to suffer such publications to be made; to invite laymen (other than relatives who may desire to be at hand) to be present at operations; to boast of cures and remedies; to adduce certificates of skill and success; or to employ any of the other methods of charlatans.

"Sec. 8. It is equally derogatory to professional character for physicians to hold patents for any surgical instruments or medicines; or to dispense, or promote the use of, secret medicines, for if such nostrums are of real efficacy, any concealment regarding them is inconsistent with beneficence and professional liberality, and if mystery alone give them public notoriety, such craft implies either disgraceful ignorance or fraudulent avarice."

ARTICLE II.—PROFESSIONAL SERVICES OF PHYSICIANS TO EACH OTHER.

"Section 1. Physicians should not, as a general rule, undertake the treatment of themselves, nor of members of their family for obvious reasons. In such circumstances they are peculiarly dependent on each other; therefore, kind offices and professional aid should always be cheerfully and gratuitously afforded. These visits ought not, however, to be obtrusively made, as they may give rise to embarrassment or interfere with that free choice on which such confidence depends.

"Sec. 2. All practising physicians and their immediate family dependents are entitled to the gratuitous services of any one or more of the physicians residing near them.

"Sec. 3. When a physician is summoned, from a distance, to the bedside of a colleague in easy financial circumstances, a compensation, proportionate to traveling expenses and to the pecuniary loss entailed by absence from the accustomed field of professional labor, should be made by the patient or relatives.

"Sec. 4. When more than one physician is attending another, one of the number should take charge of the case, otherwise the concert of thought and action so essential to wise treatment can not be assured.

"Sec. 5. The affairs of life, the pursuit of health and the various accidents and contingencies to which a physician is peculiarly exposed sometimes require the temporary withdrawal of this physician from daily professional labor and the appointment of a colleague to act for a specified time. The colleague's compliance is an act of courtesy which should always be performed with the utmost consideration for the interest and character of the family physician."

ARTICLE III.—THE DUTIES OF PHYSICIANS IN REGARD TO CONSULTATIONS.

"Section 1. The broadest dictates of humanity should be obeyed by physicians whenever and wherever their services are needed to meet the emergencies of disease or accident.

"Sec. 2. Consultations should be promoted in difficult cases, as they contribute to confidence and more enlarged views of practice.

"Sec. 3. The utmost punctuality should be observed in the visits of physicians when they are to hold consultations, and this is generally practicable, for society has been so considerate as to allow the plea of a professional engagement to take precedence over all others.

"Sec. 4. As professional engagements may sometimes cause delay in attendance, the physician who first arrives should wait for a reasonable time, after which the consultation should be considered as postponed to a new appointment.

"Sec. 5. In consultation no insincerity, rivalry, or envy should be indulged; candor, probity, and all due respect should be observed toward the physician in charge of the case.

"Sec. 6. No statement or discussion of the case should take place before the patient or friends, except in the presence of all the physicians attending, or by their common consent; and no opinions or prognostications should be delivered which are not the result of previous deliberation and concurrence.

"Sec. 7. No decision should restrain the attending physician from making such subsequent variations in the mode of treatment as any unexpected change in the character of the case may demand. But at the next consultation reasons for the variations should be stated. The same

privilege, with its obligation, belongs to the consultant when sent for in an emergency during the absence of the family physician.

"Sec. 8. The attending physician, at any time, may prescribe for the patient; not so the consultant, when alone, except in a case of emergency or when called from a considerable distance. In the first instance the consultant should do what is needed, and in the second should do no more than make an examination of the patient and leave a written opinion, under seal, to be delivered to the attending physician.

"Sec. 9. All discussions in consultation should be held as confidential. Neither by words nor by manner should any of the participants in a consultation assert or intimate that any part of the treatment pursued did not receive his assent.

"Sec. 10. It may happen that two physicians can not agree in their views of the nature of a case and of the treatment to be pursued. In the event of such disagreement, a third physician should, if practicable, be called in. None but the rarest and most exceptional circumstances would justify the consultant in taking charge of the case. He should not do so merely upon the solicitation of the patient or friends.

"Sec. 11. A physician who is called in consultation should observe the most honorable and scrupulous regard for the character and standing of the attending physician, whose conduct of the case should be justified, as far as can be, consistently with a conscientious regard for truth, and no hint or insinuation should be thrown out which could impair the confidence reposed in the attending physician."

ARTICLE IV.—DUTIES OF PHYSICIANS IN CASES OF INTERFERENCE.

"Section 1. Medicine being a liberal profession, those admitted to its ranks should found their expectations of practice especially on the character and the extent of their medical education.

"Sec. 2. The physician in his intercourse with a patient under the care of another physician, should observe the strictest caution and reserve; should give no disingenuous hints relative to the nature and treatment of the patient's disorder, nor should the course of conduct of the physician directly or indirectly tend to diminish the trust reposed in the attending physician.

"Sec. 3. The same circumspection should be observed when, from motives of business or friendship, a physician is prompted to visit a person who is under the direction of another physician. Indeed, such visits should be avoided, except under peculiar circumstances, and when they are made, no inquiries should be instituted relative to the nature of the disease, or the remedies employed, but the topics of conversation should be as foreign to the case as circumstances will admit.

"Sec. 4. A physician ought not to take charge of, or prescribe for, a patient who has recently been under the care of another physician in the same illness, except in case of a sudden emergency, or in consultation with the physician previously in attendance, or when that physician has relinquished the case or has been dismissed in due form.

"Sec. 5. The physician acting in conformity with the preceding section should not make damaging insinuations regarding the practice previously adopted, and, indeed, should justify it if consistent with truth and probity; for it often happens that patients become dissatisfied when they are not immediately relieved, and as many diseases are naturally protracted, the seeming want of success, in the first stage of treatment, affords no evidence of a lack of professional knowledge or skill.

"Sec. 6. When a physician is called to an urgent case, because the family attendant is not at hand, unless assistance in consultation is desired, the former should resign the care of the patient immediately on the arrival of the family physician.

"Sec. 7. It often happens, in cases of sudden illness, and of accidents and injuries, owing to the alarm and anxiety of friends, that several physicians are simultaneously summoned. Under these circumstances, courtesy should assign the patient to the first who arrives and who, if necessary, may invoke the aid of some of those present. In such a case, however, the acting physician should request the family physician to be called, and should withdraw unless requested to continue in attendance.

"Sec. 8. Whenever a physician is called to the patient of another physician during the enforced absence of that physician the case should be relinquished on the return of the latter.

"Sec. 9. A physician, while visiting a sick person in the country, may be asked to see another physician's patient because of a sudden aggravation of the disease. On such an occasion the immediate needs of the patient should be attended to and the case relinquished on the arrival of the attending physician.

"Sec. 10. When a physician who has been engaged to attend an obstetric case is absent and another is sent for, delivery being accomplished during the vicarious attendance, the acting physician is entitled to the professional fee, but must resign the patient on the arrival of the physician first engaged."

ARTICLE V—DIFFERENCES BETWEEN PHYSICIANS.

"Section 1. Diversity of opinion and opposition of interest may, in the medical as in other professions, sometimes occasion controversy and even contention. Whenever such unfortunate cases occur and can not be immediately adjusted, they should be referred to the arbitration of a sufficient number of impartial physicians.

"Sec. 2. A peculiar reserve must be maintained by physicians toward the public in regard to some professional questions, and as there exist many points in medical ethics and etiquette through which the feelings of physicians may be painfully assailed in their intercourse, and which can not be understood or appreciated by general society, neither the subject matter of their differences nor the adjudication of the arbitrators should be made public."

ARTICLE VI—COMPENSATION.

"Section 1. By the members of no professions are eleemosynary services more liberally dispensed than by the medical, but justice requires that some limits should be placed to their performance.

"Poverty, mutual professional obligations and certain of the public duties named in sections 1 and 2 of chapter III should always be recognized as presenting valid claims for gratuitous services; but neither institutions endowed by the public nor by the rich, nor by societies for mutual benefit, for life insurance, or for analogous purposes, nor any profession or occupation, can be admitted to possess such privilege.

"Sec. 2. It cannot be justly expected of physicians to furnish certificates of inability to serve on juries, or to perform militia duty; or to testify to the state of health of persons wishing to insure their lives, obtain pensions, or the like, without due compensation. But to persons in indigent circumstances such services should always be cheerfully and freely accorded.

"Sec. 3. Some general rules should be adopted by the physicians in every town or district relative to the minimum pecuniary acknowledgment from their patients; and it should be deemed a point of honor to adhere to these rules with as much uniformity as varying circumstances will admit.

"Sec. 4. It is the duty of physicians to recognize and by legitimate patronage to promote the profession of pharmacy, upon the skill and proficiency of which depends the reliability and elegance of remedies, but any pharmacist who, although educated in his own profession is not a qualified physician, and who assumes to prescribe for the sick, ought not to receive such countenance and support. Any druggist or pharmacist who dispenses

deteriorated or sophisticated drugs, or who substitutes one remedy for another designated in a prescription, ought thereby to forfeit the recognition and influence of physicians.

CHAPTER III—THE DUTIES OF THE PROFESSION TO THE PUBLIC.

"Section 1. As good citizens it is the duty of physicians to be very vigilant for the welfare of the community, and to bear their part in sustaining its laws, institutions, and burdens; especially should they be ready to coöperate with the proper authorities in the administration and the observance of sanitary laws and regulations, and they should also be ever ready to give counsel to the public in relation to subjects especially appertaining to their profession, as on questions of sanitary police, public hygiene and legal medicine.

"Sec. 2. It is the province of physicians to enlighten the public in regard to quarantine regulations; to the location, arrangement and dietaries of hospitals, asylums, schools, prisons and similar institutions; in regard to measures for the prevention of epidemic and contagious diseases; and when pestilence prevails, it is their duty to face the danger and to continue their labors for the alleviation of the suffering people, even at the risk of their own lives.

"Sec. 3. Physicians, when called on by legally constituted authorities, should always be ready to enlighten inquests and courts of justice on subjects strictly medical, such as involve questions relating to sanity, legitimacy, murder by poison or other violent means, and various other subjects embraced in the science of medical jurisprudence. It is but just, however, for them to expect due compensation for their services.

"Sec. 4. It is the duty of physicians, who are frequent witnesses of the great wrongs committed by charlatans, and of the injury to health and even destruction of life caused by the use of their treatment, to enlighten the public on these subjects, and to make known the injuries sustained by the unwary from the devices and pretensions of artful impostors.

"Sec. 5. Physicians ought to use all the influence which they possess to discourage pharmacists from vending the secret or other medicines of charlatans, or from being in any way engaged in their manufacture."

Dr. Harris, before reading the proposed enunciation of principles of ethics, read the following special report in explanation of the action of the general committee on code:

"*To the President and Members of the House of Delegates*

"Your committee has given extended and careful thought to the proposed revision of the code of medical ethics referred to it for consideration. As you will note on caption of report, the word 'code' has been eliminated, and the expression 'The principles of medical ethics of the American Medical Association' adopted as adequately descriptive. In reference to this change it is proper to say that such action on its part is based on the idea that the American Medical Association may be conceived to occupy some such relation to the constituent State associations as the United States through its Constitution holds to the several States. The committee, for this reason, regards it as wiser to formulate the principles of medical ethics without definite reference to code or penalties, thus leaving the respective States, etc., to form such code and establish such penalties as they may regard to be fitting and proper for regulating the professional conduct of their members; provided, of course, that in so doing there be no infringement of the established ethical principles of the association. The committee regards as wise and well intended to facilitate the business of the parent organization and promote its harmony, this course, which leaves to the State association large discretional powers concerning membership and other admittedly State affairs.

"Your committee has retained to a large extent the phraseology of the existing code, while aiming at condensation of expression and a better understanding of some of its statements.

"The report of the committee has been reached unanimously without discussion or distrust on the part of its members, each aiming to formulate a result based on principle alone, and without regard to any past or present disagreements or misunderstandings whatsoever.

"Such being the case, the committee invites your candid and unprejudiced attention and action to the results of its labor, feeling that at least some good has been accomplished.

"Respectfully submitted,

"E. Eliot Harris, Chairman;
"T. J. Happel,
"W. H. Welch,
"Joseph D. Bryant."

The report was unanimously adopted.

There was no discussion of the proposed enunciation of principles. Dr. Harris dwelt upon the fact that the subcommittee had been unanimous and that the report had been unanimously adopted by the general committee. He moved the adoption of the committee report, which consisted of the Welch-Reed preamble, the first part of the original report to the convention, with the elimination of the word "code" from the title, the insertion of three sections from the proposed Reed document, and the elimination of the second part of the original committee report.

Dr. Reed instantly seconded the motion to adopt, expressing the hope that the discussion, if any, would be brief.

There were cries of "question," and it was put and carried with a cheer.

When this final report was presented to the house of delegates, it was adopted by a unanimous vote amid cheers.

Officers Elected.—*President*, J. H. Musser, Pennsylvania; *First Vice-President*, E. C. Savage, Tennessee; *Second Vice-President*, Isadore Dyer, Louisiana; *Third Vice-President*, C. Lester Hall, Missouri; *Fourth Vice-President*, George H. Jenkins, Iowa; *Treasurer*, H. P. Newman, Illinois; *Secretary*, George H. Simmons, Illinois; *Trustees*, William H. Welch, Maryland; Miles F. Porter, Indiana; M. L. Harris, Illinois; *Judicial Council*, Frederick Holme Wiggin, New York; G. B. Gillespie, Tennessee; D. C. Peyton, Indiana; T. C. Martin, Ohio; J. B. Roberts, Pennsylvania; Christopher Tompkins, Virginia. *Orators:* In Surgery, W. J. Mayo, Minnesota; in Medicine, George Dock, Michigan; in State Medicine, H. M. Biggs, New York.

Place of Meeting.—Atlantic City was selected for the next place of meeting.

The New Orleans Meeting.—The official registration, 2,017, gives a fair idea of the attendance, as it is estimated that there were at least 1,000 more present. The meeting was especially noteworthy because the character of the scientific work was far above the average, but it is also memorable because of the harmony and good feeling that prevailed, and that, too, despite the dethroning of that troublesome idol, the code of ethics, and its relegation to the more appropriate, but no less honorable, position of "a suggestive and advisory document." But other pleasant memories will linger in the minds of those who were present at this great gathering—the recollections of the warm-hearted Southern hospitality of the people of the great crescent city.

SECTION ON PRACTICE OF MEDICINE, THURSDAY, MAY 7.

Combined Meeting with the Section on Hygiene and Sanitary Science.

SYMPOSIUM ON TYPHOID FEVER.

On the Sources and Manner of Infection of Typhoid Fever.—Dr. Wm. H. Welch of Baltimore said that there was no missing link in the chain of proof that the typhoid bacillus was the cause of typhoid fever. At present there

was no positive or experimental proof that the origin of the disease could be through the respiratory tract; it could only arise from the injection of the typhoid bacillus into the alimentary canal. The bacillus was eliminated from the body through the fæces and the urine and, in very rare instances, it might be found in the sputum, but this was so rare as not to deserve consideration. He emphasized the importance of the knowledge of the bacillus being found in the urine of typhoid-fever patients, even for a long time after convalescence had become established. This fact was a very important one from a prophylactic consideration. Another important factor in the causation of typhoid fever was the dosage. The source of the infection was, *the typhoid patient.* If one could prevent the typhoid bacillus from gaining an exit from the typhoid patient he believed that typhoid fever could be made to disappear from the world. He referred to the experimental work of Reed, Vaughn, Shakespeare, and others, in which it was shown that the majority of the cases were not attributable to drinking water, but to a direct transmission from one typhoid-fever patient to another; in the cases of the soldiers the disease was transmitted by things about the tents, articles of bedding, etc., and they brought out the agency of flies and other insects in the transportation of the disease. The bacillus could be transmitted in various ways, but he believed that in many communities the solution of the prevention was likely to be found in the powdered infiltration, or sand infiltration. He thought we were far behind the continental countries in this respect. Typhoid fever was occasionally traced through the ingestion of vegetables or raw foods; also through the dust in the air. He also took up the consideration of the contamination of milk occurring chiefly through the air or through the water used in washing out the cans. Milk, he said, was an excellent medium for the growth of the bacillus. Milk had been the cause of many epidemics.

Some Unconsidered Hindrances in the Prophylaxis of Typhoid Fever.—Dr. John S. Fulton of Baltimore read this paper and said that knowledge of the natural history included all facts essential to successful prophylaxis, yet prophylaxis was a failure, for typhoid was one of the most common of continued fevers. Failure in prophylaxis was, in most part, explained by three considerations, as follows: (1) In most cases it was not recognized. Of the ambulant and mild cases, a vast majority escaped recognition; those cases at the extremes of life, a vast majority was not recognized; the plain, uncomplicated, bedridden cases, 40 per cent., were unrecognized. Fifty per cent. of all such cases, shared by physicians all over the country, were chargeable to a serious default of education and to the delusion that malaria was a considerable cause of mortality. (2) The view that typhoid fever was distinctly a disease of large communities was erroneous. He said that the rural mortality was nearly three times that of the largest cities and that typhoid fever was distinctly a rural disease, and this he illustrated from census reports. (3) The general prophylaxis in large cities, though measurably effective in the defense of cities, could not, by its widest conceivable extension, have a marked effect upon the total typhoid mortality in the country. Municipal prophylaxis was concerned only with the least part, and was not in immediate relation with this least part of the general morbidity from typhoid fever. He said that the largest prime factor in dissemination was occurrence in rural districts where the disposal of human excrement admitted of wide distribution of the bacillus by wind, water, animals, and insects. Prophylactic measures consisted in the general care of the water and food, the screening of privies, the destruction of flies, and other insects, and their exclusion from dwellings, etc. He emphasized the need of a rapid, simple, and cheap method of disinfecting fæces.

Dr. John H. Musser of Philadelphia thought that, with the more modern means for making diagnoses, an earlier diagnosis should be had. He advised the use of urotropin as a means of lessening the number of bacilli contained in the urine of these patients. This drug would also tend to prevent one of the complications of typhoid, *i. e.* cystitis

Dr. DeLancey Rochester of Buffalo, N. Y., advised the use of large amounts of chloride of lime for disinfecting the stools.

Dr. James J. Walsh of New York referred to a large city in this country where, for ten years, the introduction of a filtration plant had been held back because of political reasons. Three thousand deaths occurred, and yet nothing was done toward punishing anyone for criminal negligence.

SYMPOSIUM ON YELLOW FEVER.

The Mode of Transmission of Yellow Fever.—Dr. James Carroll, U. S. A., opened the discussion of this topic. He discussed some of the older theories and the lessons learned in the past from observation and experience alone. The more modern theory was based on the supposed bacteriologic origin of the disease. Finley's theory of the transmission of the disease by means of the mosquito was considered. He claimed that yellow fever could be produced by the mosquito only. Disinfection and fumigation was a perfectly useless expediency, entailing a useless expense of time and money.

Dr. Stamford E. Chaillé referred to certain notable investigations made by Reed, Carroll, Agramonte, and others which had contributed four sets of precious facts: (1) Fresh blood or its serum taken from a case of yellow fever during the first days of the attack would give the disease, if hypodermically injected into a non-immune. Hence the blood contained the poison. (3) The female stegomyia fasciata mosquito, serving as an intermediate host, could convey the poison to non-immunes. (3) Excluding all mosquitos, fomites prepared and kept under all the known conditions universally known to be the very best, for supplying the most virulent fomites, failed to infect seven non-immunes extraordinarily exposed to said fomites. (4) Disregarding filth and fomites, because two years' warfare against them had proved ineffectual, and limiting sanitary measures solely to excluding imported cases, to isolating every home case, and preventing in every possible way the access of mosquitos, these measures were followed in Havana by the total disappearance of all home cases from September 28, 1901, to May, 1903. He said that the case of fomites *versus* stegomyia was of the utmost importance for prevention and commerce and deserved consideration. The only advocates of fomites known to him, who had published their views, were two distinguished sanitary officers, Punnell of Mississippi and Souchon of Louisiana. He then took up the arguments of both to prove that the stegomyia was not the sole cause, but that fomites were also a cause. He said that Carter, writing in favor of the stegomyia, claimed that every disease, having an intermediate host, was propagated solely by its special host and never by fomites. He doubted whether we could be justified at present to accept this as a final conclusion. Dr Chaillé, so soon as he was convinced that mosquitos followed routes of travel, and that the stegomyia was a conveyer of yellow fever, embraced the stegomyia as a welcome substitute for fomites. In fact, he had never secured satisfactory evidence of the proof of a single case either by direct contagion or of infection by fomites. He concluded his paper as follows: The probabilities now are that the stegomyia, the only cause yet proven, was the sole cause for the dissemination of yellow fever; time was required to convert these probabilities into certainty. Boards of Health, should they neglect any practical measure of warfare against the stegomyia, would deserve the severest punishment of the worst criminals. Southern Boards of Health were excusable for over-precaution against yellow fever. States adjacent to Louisiana had power, by sanitary restrictions, to strangle the commerce of New Orleans, and Louisiana should not abandon the disinfection of fomites until approved by said States. Boards of Healths were representatives of the people, and were justifiable in continuing to disinfect

fomites as long as public opinion favored this measure, and until the probability of its inutility was converted into certainty.

Dr. Edmund Souchon, President of the Louisiana State Board of Health, continued the discussion. He said the foremost perplexity of the responsible officers was the question of the treatment of fomites; from the known experiments of Reed, Carroll, Guitéras, and Ross it was contended that the disinfection of fomites was unnecessary. To these experiments the responsible officers oppose the fact that they were made at a time of the year when yellow fever was not at its worst, except, perhaps, the early experiments of Ross. Again it should be considered that 30 per cent. of the non-immunes bitten by infected mosquitos did not develop yellow fever. He thought, therefore, it was unreasonable to expect that all experiments made with fomites should develop yellow fever. The responsible officers did not contend that fomites do not transmit yellow fever; they modestly state that they do not know. He said that for the present and until further progress the responsible officers were unwilling to make any change in the quarantine regulations against yellow fever.

Dr. C. W. Stiles of Washington said there were certain biological facts in the consideration of yellow fever. The cause of the disease belonged to one of three different groups: (1) bacterium, (2) flagelia, and (3) sporozoa. The entire history of the disease, with its short incubation period, etc., shows that the organism was probably reproduced by non-sexual methods. The bacterium seemed to be excluded by the history of incubation in the mosquito. Regarding the flagelia, nothing was known regarding its sexual development. He thought the parasite which was the cause of the disease possibly was a sporozoa.

Sources and Manner of Infection of Plague.—Dr. W. J. Calvert of St. Louis, Mo., read this paper, giving a historical sketch with reference to great pandemics, more especially to the present. He considered the features of the bacillus pestis, its viability and possible modes of dissemination, and portals of entry into the human system. He said that no matter if it was stamped out in this country it would be likely to reappear so long as such places as Canton and Hongkong existed.

Prophylaxis of Plague.—Dr. J. J. Kinyoun of Philadelphia said that the *sine quâ non* was the accurate diagnosis of the first case, and that the clinical forms were so varied that error in diagnosis of first cases was the rule. Plague might resemble anthrax, tonsillitis, mumps, diphtheria, erysipelas, pneumonia, acute pleurisy, malignant pericarditis, endocarditis, typhoid, typhus, relapsing and malarial fevers, acute dysentery, miliary tubercle, septicæmia, pyæmia, and syphillis. These forms of plague and its insidiousness and the inexperience of the profession rendered plague one of the most difficult to recognize. For diagnosis a bacteriological examination was essential. He then considered the measures to be adopted in caring for such patients, dividing up the treatment into the following different heads: (1) Isolation pending a diagnosis; (2) Segregation under medical supervision of contacts and suspects; (3) Disinfection of premises; (4) Sanitary measures in immediate vicinity; (5) Destruction of vermin and their examination; (6) General measures against the dissemination of the disease, *i. e.* then referred briefly to the consideration of maritime commerce, the personnel of vessels, the cargo, the vessel itself. Under the heading of maritime quarantine, he considered the measures to be taken in a port where plague existed both in its detection and eradication and the measures to be taken to prevent its spread.

Dr. F. G. Novy of Ann Arbor, Mich., continued the discussion. He said that in plague we had a well-defined disease caused by a well-defined organism. The organism can be readily seen and recognized under the microscope in every case brought to the post-mortem table. The experiments can be made to demonstrate the disease in animals to any one, and the organism complies with every requirement. The question came up, "Will this organism always produce the disease?" He emphasized the fact that plague was essentially a disease of animals and primarily was not a human disease. The disease was transmitted by the bites of animals, such as the rats or rodents of China. How the disease was communicated to the human being; what was the portal of entry, was a very difficult question to answer and possibly never would be answered satisfactorily. The virulency of the germ decreased the longer it was kept in artificial culture. The organism he did not consider to be very resistent and could be easily destroyed. Besides isolation of the sick, disinfection, segregation, etc., he said we have a powerful method of controlling the disease, *i. e.* with the serum.

Arthritis Deformans.—Dr. Thomas McCrae of Baltimore read this paper, reporting a study of a series of 110 cases from the Johns Hopkins Hospital. Reference was made to the obscurity of the pathology and our ignorance regarding the disease. The two great types of the disease were mentioned and the distinction between them. Certain cases of this series apparently showed the co-existence of these two different grades. The whole series showed an equal number in the two sexes, but a striking small number among the colored, only four out of 100, a proportion of twenty-six to one colored. The native born were ninety-six. There was an absence of a history of exposure to cold or wet. There was a family history of arthritis in forty-four. For clinical study the cases were divided into four groups: (1) Heberden's nodes; (2) the polyarticular form; (3) the monarticular form; (4) spondylitis. Of the first group no cases are in this series unless the joints were involved. Of these there were nine, but in only two of these were the manifestations severe. The polyarticular forms were in the largest group, ninety-four, including two cases of "Still's disease." In half of these the onset was before the age of thirty years. Special stress was laid on the acute character of many of these. In forty-one the onset was sudden. Two main classes of cases can be recognized, a slow progressive type and one in which there were repeated acute attacks. There were thirty cases in this latter group. Such cases were nearly always mistaken for acute articular rheumatism. The distinguishing features of these cases were dwelt upon and the importance of other infections, such as influenza in bringing on attacks. The usual high pulse rate and the temperature curve were noted. Especial stress was laid on the importance of the study of the early cases if we are to clear up the disease. The diagnosis and treatment were also discussed. Of the monoarticular form there were three cases. Their doubtful character was discussed. The fourth group, spondylitis, comprised twenty-two cases, thirteen of spinal involvement only and nine with other joints in addition.

In fifteen the whole spine, and in seven only a portion were involved. The work of Dr. Goldthwait of Boston was noted in this group. The importance of knowing especially the features of the local involvement was emphasized and the points in the diagnosis and treatment.

Albuminuria in Diabetes Mellitus: Its Importance as a Factor in the Causation of Coma.—Dr. Arthur R. Elliott of Chicago read this paper and said that the following conclusions seemed to be warrantable: (1) Albuminuria was a frequent occurrence during the progress of diabetes, one-third of all cases manifesting this symptom at some time during their course. (2) Albuminuria in diabetes may, for clinical purposes, be divided into two varieties, toxic and degenerative. (3) Toxic albuminuria was generally of acute onset, arising during the later stages of the severe form of the disease, as the result of irritation of the tubular epithelium, producing hyaline degeneration thereof and due to the presence of acid toxins in the blood and urine. (4) Toxic

albuminuria was an invariable precedent and accompaniment of coma, and may be regarded as one of the greatest prognostic significance. (5) Toxic albuminuria and its associated renal changes was the final determining cause of coma diabeticum, by producing a heaping up of sugar and toxins in the blood, through diminished permeability of the renal secreting structure. (6) Degenerative albuminuria occurs with great frequency during the progress of the mild type of the disease, and was of renal origin and produced by a gradually developing nephritis, which arose from prolonged hyper-function and impairment of renal nutrition. (7) The appearance of albumin under the circumstances, while of little immediate significance, was of the greatest eventual importance, as indicating thei ntrusion of chronic nephritis into the already manifold clinical difficulties. (8) A few cases of albuminuria diabetes may be produced by venous stasis due to cardiac asthenia, and under such circumstances will be associated with other evidence of heart failure. (9) Albuminuria in diabetes was never devoid of importance. It may be of the greatest significance, and was always of sufficient import to receive the earnest attention of the clinician.

FOURTH DAY—MAY 8.

The Passing of Chronic Rheumatism.—Dr. JAMES J. WALSH of New York read this paper. He said there were four different achey conditions which were often called chronic rheumatism, but without any good reason. The most common form of pseudo-rheumatism was the relaxation of joints which occur in the ankle, and which was known as flat-foot, or which followed the dislocation of joints producing tissue changes which made the patients very susceptible for all their after-life to changes in the weather. Just as there were relaxations of the ankle joint, so could there be relaxations of other joints. A second form occurred in the so-called occupation neuroses. A third form of vague pains which would often be attributed to rheumatism was neuritis. Persons who were exposed to the weather, and who used one set of muscles more than another, especially if there was an absorbtion into the system of such toxic substances as lead and alcohol, were especially prone to a neuritis in the nerve supplying the over-worked muscles. Again, a certain number of so-called chronic rheumatism cases in this country presenting evidences of joint degeneration following acute attacks of arthritis, were undoubtedly not genuinely rheumatic in character, but were of gouty nature. He said that, according to recent statistics, gout was only three-fourths as frequent in this country as in England. Acute gout was very difficult to differentiate from acute rheumatism. After considering briefly three forms of rheumatoid arthritis, he stated that it was easy to understand that but little space was left for the so-called chronic rheumatism. Certainly cases of true chronic rheumatism that was of a progressive pathological change in joint tissues, for which no other cause except rheumatism could be found, were very rare, and he confessed that he had never seen such a case.

Hæmoglobinuric Fever; Its Causes and Treatment.—Dr. WALTER SHROPSHIRE of Yoakum, Tex., read this paper. A report of 202 cases collected showed 61 treated without methylene blue, or with less quinia than 5 grains per diem, of which 26.2 per cent. died and 73.8 per cent. recovered; while of 112 cases treated with 20 grains or over of quinia, 16.9 per cent. died and 83.1 per cent. recovered. Four were treated with methylene blue, with one death and three recoveries. It was shown that quinia not only lowered the death rate, but also lowered the percentage of recurring paroxysms. The following facts were presented: (1) That this disease always occurred in persons suffering repeated attacks of malaria; (2) that it nearly always followed one or more paroxysms of malaria at the proper time for its next exacerbation; (3) it had all the characteristics of malaria, chill, fever, and sweat; (4) that where adequate examination of the blood was made, the hæmatozoa of malaria was found; (5) its habitat, that of the most violently malarious districts. After a review of the effects of quinia it was indeed difficult, if not impossible, to conclude logically that it could produce hæmoglobinuria. Summing up the evidence for and against quinia as a cause of this disease, he said that 29.4 per cent. of physicians affirmed and 70.59 denied it. When quinia was suspended, 73.8 per cent. recovered; when quinia was administered, 83.1 per cent. recovered. Distinct recurrences of attacks after the first appearance of black water in non-quininized patients, 9.8 per cent.; distinct recurrences of attacks after the first appearance of black water in quininized patients, 4.4 per cent.; of cases occurring from quinine alone 0 per cent.; of cases occurring from malaria without quinine, 15 per cent.; of cases in which quinine was supposed to aggravate, 5.9 per cent.; of cases in which quinine was thought not to aggravate, 55.41 per cent. This gave a preponderating evidence against quinia as a causative factor in the production of this disease. In the treatment of this condition he advised giving 40 grains of quinine per diem, either intravenously or hypodermically until the next period of an exacerbation was safely passed; then it should be discontinued for three or four days and then repeated in 20 to 30-grain doses every four to six days until five or six weeks have passed without a paroxysm. Attention to liver and bowels was emphasized with the ingestion of large doses of very hot water.

Some Clinical Aspects of Tuberculous Peritonitis.—Dr. JOSEPH EICHBERG of Cincinnati read this paper, and said that among the many startling results that have followed the introduction of laparotomy, exploratory and curative, none showed a more decided departure from beliefs of a former generation than the present attitude of the profession with regard to tuberculous peritonitis. On the basis of post-mortem finding various classifications had been made, but the simplest was the dry and the exudative, included under the latter head the caseous and purulent varieties. From a clinical standpoint, Hawkins divided them into four varieties, as follows: (1) Latent; (2) severe, with ascites and a spontaneous tendency to remissions or encapsulations; (3) cheesy-purulent form, with frequent formation of large caseous masses and adhesions; (4) fibro-adhesive form. He said there was much difficulty in establishing any basis of classification, either pathological or clinical. Laparotomy did not always establish a diagnosis. Good results have followed simple incision, irrigation of the cavity, drying of the peritoneum, resection of diseased parts, and other modifications. The essential feature seemed to be incision. He stated that the percentage of recoveries without operation for all ages, with or without complications, was greater than with operation. In five and a half years Herringham observed 25 cases diagnosed as tuberculous peritonitis, of which 19 recovered without operation, and 3 were improved. He found the only justification for operation was a return and increase of the ascites, after puncture. Hawkins reported 59 cases which recovered, all but 3 being treated by internal medication. Czerny cautioned against expecting too much from the operation. He believed that the opinion that a diagnosis of tuberculous peritonitis called for an immediate laparotomy was erroneous, not to say vicious.

Tuberculosis in the Negro.—Dr. SEALE HARRIS of Union Springs, Ala., read this paper. He said that tuberculosis was unknown among the native Africans until the infection was carried to them by slave traders and colonists. It was a rare disease among the slaves in the Southern States, because the hygienic methods of living enforced among slaves prevented their becoming infected. Statistics showed an increase of tuberculosis among the negroes during the past forty years. Then followed statistics for Southern States and for his home in Alabama. Among the causes he gave for increase of tuberculosis among the negroes, comparing them with the white population, were the small lungs, less lung capacity and less chest expansion. The filthy habit of spitting was one of the great causes of the dissemination of the disease. Syphilis was a very great

predisposing factor in tuberculosis, and the increase in syphilis in the past thirty years had been *pari passu* with that of tuberculosis. He then considered the methods to pursue in limiting an infectious disease like tuberculosis, such as increasing the strength and vitality of the individuals of the race, thereby rendering their tissues an unsuitable soil for the invasion and propagation of the specific germs of the disease and in preventing his exposure to the infecting agent, as by the isolation of those already infected and by destroying the organisms causing the disease.

Should the Tuberculous Patient Know the Truth Regarding His Condition?—Dr. C. P. Ambler of Asheville, N. C., read this paper. He believed it to be the duty of the physician to explain to the patient the dangers to himself and to others; to point out where he was most apt to make mistakes; to give explicit directions regarding his hygienic life, including diet, exercise, work, physical or mental application, secretion and excretion, sexual relations, and, in fact, to go fully into the whole question of the hygiene of life. Such instructions should apply to the incipient as well as the advanced cases. To get the coöperation of the incipient cases they must know the truth. The laws of health demand that the patient fully realize the danger to himself and others. The patient should be appealed to that it was unkind to his friends not to make every effort to protect them. The education of the public, and the careful education of the patient as regards infection of others would accomplish more than legislation. In the fight against the spread of tuberculosis the patient should first of all know the truth regarding his condition.

Officers Elected.—For *Chairman*, Dr. Alexander Lambert of New York; for *Secretary*, Dr. J. S. Miller of Chicago; for *Member of House of Delegates*, Dr. Frank A. Jones of Tennessee.

INTERNATIONAL CONGRESS OF THE MEDICAL PRESS.

Held at Madrid, Spain, April 20-22.

In accordance with the rules of the International Medical Press Association, which were adopted at a meeting held at Monaco last year, the second international congress was held in Madrid on April 20, 21, and 22, the three days immediately preceding the opening of the International Medical Congress.

The meetings were held in the hall of the University of Madrid, under the presidency of Dr. Cortezo, chief health officer of Madrid and proprietor of *El Siglo Medico*. The secretary of the Congress was Dr. Larra y Cerezo, editor of *La Medicina Militar Española*. At the opening session, the Minister of Public Instruction, Señor Allende Salazar, presided. An address was delivered by Dr. Larra, in which he spoke of the organization of the present congress, outlined the work to be done, and reviewed briefly the history of the International Medical Press Association. The president, Sr. Cortezo, then delivered an address of welcome to the members present, speaking in French, Spanish, Italian, and German. Addresses were then made by the delegates of the various national medical press associations, and then the Minister of Public Instruction declared the congress open.

In the evening the members were entertained at dinner by the president of the congress.

The *second session* was held on Tuesday morning. Dr. Tolosa Latour of Madrid read a paper on "Intellectual Property in Relation to the Medical Press," in which he contended that to the author of any memoir, article, or letter belonged the right of publication. In the discussion some of the speakers denounced the publication of society reports in the medical journals, contending that such publication discouraged the careful preparation of papers read before societies. Dr. Espina urged a more active propaganda against tuberculosis by the medical press, and Dr. Vargas added to his suggestion the recommendation that medical journals should keep standing upon their covers counsels looking to the suppression of this disease. Dr. Pulido then read a paper on the "Relations between the Medical Press and the State Governments," in which he expressed the opinion that medical journalists could be of great assistance to legislators if the latter would only take their advice.

The *third session* was held in the afternoon of the same day. Dr. Larra read a paper on the "History of Medical Journalism" in Spain, which country, he said, was the second to give birth to a medical periodical. This was the *Efemérides Medico-matritenses*, published by the Academy of Medicine in 1734. Dr. Blondel of Paris read a paper in which he developed at greater length his remarks in discussion of Dr. Latour's paper of the morning, regarding the publication of reports of society meetings in medical periodicals. Dr. Male then presented a communication on popular medicine and the manner in which it might be permissible to publish essays on medical subjects in the lay press. After the adjournment the members were entertained at a Basque ball game. In the evening the Press Association of Madrid gave a reception in honor of the medical journalists.

The *fourth session* was held on Wednesday morning. Dr. Barberá read a paper on "Medical and Pharmaceutical Journalism in Valencia." Dr. Pascual of Gerona presented a communication on "The Need of a Methodical Index, with Abstracts of Articles Published in the Medical Press." Dr. Perez Noguera read a paper on "The Medical Press in Its Relation to Military Surgery"; Dr. Martínez Vargas one on "The Medical Press and Medical Teaching," and Dr. Monmeneu one on "The Influence of the Medical Press on General Culture." Dr. Codina introduced a motion in condemnation of periodicals which, under the cloak of medical science, had no other aim than the pushing of proprietary remedies. A paper was also read deprecating the publication in one country of medical periodicals in the language of another country, the attack being directed mainly against the publication in Paris of journals in the Spanish language. At the close of this session the members breakfasted together in the Alhambra Theatre.

The *fifth session* was devoted to a discussion of the regulations of the International Medical Press Association. The article which excited the most lively discussion was the one defining literary property, in which it was held that oral lectures could not be published without the permission of the authors. Opinions on this point were so evenly divided that a roll call was necessary before the president gave his decision. Finally it was carried in the affirmative, and the regulations were definitely adopted. The city council gave a reception to the members in the evening. Dr. Cortezo, the president of the Congress, was chosen president of the International Medical Press Association to succeed Dr. Cornil of Paris.

The management of the Medical Press Congress was admirable, the program being carried out exactly as announced, without confusion, and in a seemly manner—furnishing thereby a most marked contrast to the pandemonium resulting from the utter lack of executive ability displayed by the officers of the International Medical Congress.

Surgery of the Prostate.—Sir Thomas Myles believes that the perineal route in the majority of cases is to be preferred to the abdominal, for the complete removal of diseased prostates for the following reasons The advantages of the method are: It guarantees that the bladder shall be kept empty; that no hemorrhage shall take place, and that every stage of the operation is in sight of the operator. Against the perineal method are the facts that it requires a bigger and more elaborate dissection; that it takes more time until one acquires practice and that there is an element of danger in detaching the rectum from the central tendinous point of the perineum. —*The Medical Press and Circular.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 9, 1903:

	Cases.	Deaths.
Measles	314	19
Diphtheria and croup	405	51
Scarlet fever	323	18
Smallpox	..	..
Varicella	108	..
Tuberculosis	293	175
Typhoid fever	25	5
Cerebrospinal meningitis	..	..

The Diagnosis of Chronic Interstitial Nephritis Based upon Physical Signs, Chiefly Cardiovascular.—Charles Louis Mix considers it an error to approach the problem from the point of view of the urinary examination alone, as many cases of chronic interstitial nephritis fail to show any albumin. The vascular changes are important. Practically, the arteries are those of arterial sclerosis, firm, tough, and tortuous. The renal pulse is one of abnormally high tension, but in a few cases the tension is not increased, especially in cases of failing cardiac compensation. According to Traube's old statistics cardiac hypertrophy is present in 93 per cent. of the cases of chronic interstitial nephritis. This hypertrophy is compensatory, the increased cardiac power promoting increased diuresis for the purpose of sweeping out the toxins, but it also has its disadvantages, as hemorrhages are likely to occur. Hæmaturia is rare, but there may be epistaxis, hemorrhage from the bowels in rare cases, retinal hemorrhages with amaurosis, auditory hemorrhages and, most of all, cerebral hemorrhages. It is the physician's duty to keep an even tension in the radial pulse. Cardiac stimulants should never be given unless cardiac failure is evident; and when arterial pressure is very high, it should be lowered by nitroglycerin or the nitrites.—*Medicine*, March, 1903.

Starvation as a Therapeutic Agent.—Charles Douglas says that the selection of patients requiring starvation for a time, opens up a very wide field, inasmuch as we find them of all ages, and the sicknesses of a wide range in character. When we consider the anorexia usually produced in all febrile diseases, and also the direct range of its intensity with the height of the fever, we see at once how nature follows a common law of lessened necessity for food in all acute febrile disturbances. We should also remember nature's law in those with unhealthy or overworked digestive organs when suffering from acute febrile disturbances. Especially in this latter class it is necessary to apply this starvation regimen, as these patients very commonly suffer from an increased craving for food, rather than the anorexia which should accompany the condition. In other words, the physician should always apply this regimen when he knows that the clinical condition of the patient prevents perfect digestion of the food, and consequently if allowed it will add another source of high temperature, and consequently a mixed infection of toxæmia will be the result, with the difficulties of diagnosis and treatment materially increased. The author reports a number of cases illustrating the success of the starvation treatment in nephritis, gastroenteritis, pneumonia, and scarlet fever.—*Detroit Medical Journal*, March, 1903

Observations upon the Hypnotic Action of Hedonal.—Frederick L. Hills reports cases of chronic mania, recurrent mania, melancholia with agitation acute melancholia, melancholia with stupor, senile degeneration, puerperal mania, epilepsy, asthma, etc., in which hedonal was given as a hypnotic. He believes that it has a value greater than that of sulphonal or trional, not so long continued as that of paraldehyde or chloral, but safer in its action than any of these. It seems to be entirely devoid of any ill effect upon the organism, safe in the presence of valvular heart lesions, and effectual in producing from four to eight hours of quiet sleep, from which the patient awakes refreshed. Its action is manifested in from one-half to one hour after administration. Its field of usefulness is in cases of neurasthenia, hypochondriasis, melancholia of the milder types, and various nervous diseases attended by insomnia without marked mental excitement or great motor restlessness. It is best to administer it in wafers. The best action has been obtained from doses of 20 to 30 grains. Only in very refractory cases is a larger dose necessary,—*The Therapeutic Gazette*, March 15, 1903.

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending May 9, 1903:

SOME UNUSUAL CASES OF APPENDICITIS.*

BY ROBERT F. WEIR, M.D., HON. F.R.S.C., ENG.,
PROFESSOR OF SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE something new that is ever presenting itself in the operation for the relief of appendicitis is a matter of common remark among surgeons. It recalls the similar observation which was made in earlier years when strangulated hernia was more frequent than it now is. It is this appearance of the unexpected that renders this particular disease of great interest to the surgeon, but makes just the otherwise invidious statement that a considerable experience is requisite to meet its varied conditions. Many of the phases of appendicitis are often only recognized at the time of the operation, such as, for instance, an extensive and spreading peritonitis, or pus infiltration in the dorsal gutter or in the pelvis, etc., and all these demand the highest surgical skill. Add to these the post-operative complications of sub-hepatic or sub-diaphragmatic and other abscesses, and of fecal fistula or of early or late intestinal obstruction, or a septic pneumonia or pleurisy, and we have a total that is sufficient to tax the best trained mind and hand.

The ordinary run of cases is apt to make a surgeon too confident of his ability to meet a rapid or obscurely progressing attack of appendicitis. It is the unusual case that most disturbs his equanimity, and hence we all can aid each other, and particularly our juniors, by publishing each one his little mite of experience in the difficult cases; and it is with this intent I have ventured to narrate here a few instances in which somewhat unusual conditions were found in which the diagnosis was obscured, believing that the members of this society, made up as it is of men of large practice, will not only appreciate the points presented but will also corroborate the statements just made, and will add, I hope, by their contribution of other or similar cases, to the general instruction on this subject.

I. Internal Intestinal Strangulation from an Elongated Inflamed Appendix.—The first case to which I ask your attention is one in which much obscurity presented itself, and in which when judgment advanced to the point of a laparotomy, to meet whatever might be thus revealed, an elongated appendix was found with the end recently glued to the side of the lumbar vertebra, and under it a large loop of small intestine had thrust itself and had become strangulated to a dangerous degree. The details are as follows: The patient was a young woman, aged twenty-one years, who was admitted to the Roosevelt Hospital on November 18, 1902, with the history that forty-eight hours previously, having up to then been in robust health, she was seized with general abdominal pain and vomiting. This latter symptom had persisted, the matters ejected being of a greenish color. Her bowels had not moved for four days, though many purgatives had been used. Nothing was felt in examination of the abdomen, no rigidity or distension was present. There were no special points of tenderness, though pain was complained of whenever and wherever pressure was made on the abdominal walls. When, however, her attention was distracted, pressure was well borne on previously complained-of places. Nothing was detected in the right iliac fossa, and no history of previous appendical attacks could be elicited. She voluntarily turned from side to side. The vomiting continued frequently during the day of admission and the pain occurred at intervals. There was, however, some increased leucocytosis (13,000). In brief, the symptoms were only vomiting and unreliable pain in an apparently hyperæsthetic young woman with an unchanged facies. Temperature, 99–100°; pulse, 88–96. Castor oil by the mouth and large enemata were given. The next day the vomiting held up until the afternoon, possibly from a dose (8 m.) of Magendie's solution given at 6 A.M. to relieve her abdominal pain. Late in the day vomiting returned, still with absence of rigidity or distension and with a temperature the same as yesterday, but by the next morning, November 20, a change showed itself, in that a central abdominal meteorism presented itself with a marked change in her facial aspect, and the vomited matters became browner and more offensive in odor, the temperature and pulse remaining the same. A leucocyte count that morning showed an increase to 17,000. An exploratory laparotomy by a median incision was resorted to by Dr. Weir at 3.30. This revealed in the right iliac fossa near the pelvic edge a mass of contracted purplish-brown small intestines which indicated an obstruction, which a little search showed to be due to a band that ran upward toward the root of the mesentery, and which, when first seen, was believed to be a Meckel's diverticulum, under which a loop of some eight or ten inches of intestine was firmly bound down and constricted. While endeavoring to trace this, it yielded under the traction of the fingers, and the distal end of a five or six-inch long appendix came into view and released the constricted loop of intestine, which speedily began to resume its normal color and size. The accompanying diagram (Fig. 1) shows better than words how the constriction was exerted. The end of the appendix was bulbous, deeply congested from inflammation, and was found to have been attached to the right side of the lower lumbar vertebræ just above the sacral rim of the pelvis. The adjacent loop of intestine showed some recent fibrinous exudation. The appendix was removed and its stump cauterized, inverted into the cæcum and buried by a purse-string suture. The abdominal wound was closed by layer sutures without drainage, as the peritonitis was so very limited. The patient made a satisfactory recovery.

Since then I have seen a somewhat similar case in which the symptoms did not become acute, but the moderate tenderness, with an ill-defined swelling in the right ileac fossa, suggested a mild appendicitis. After waiting a while until tenderness abated and the swelling partially subsided, an "interval" operation was undertaken and revealed a band from the

*Read at a meeting of the New York Practitioners' Society, March 6, 1903.

omentum to the cæcum, under which was caught a loop of small intestine. This had lasted long enough to groove deeply the bowel.

The next case was supposed, until the operative incision was made, to be one of simple strangulated femoral hernia, but it was then discovered to be a *hydrocele of a hernial sac with an acute appendicitis*.

The patient, a woman of forty years, came into the Roosevelt Hospital on February 5, 1903, complaining of a small persistent swelling of varying size in the right groin, the origin of which she could not give, and which had existed over a year. This tumefaction did not trouble her in any special way until about three weeks before her entry

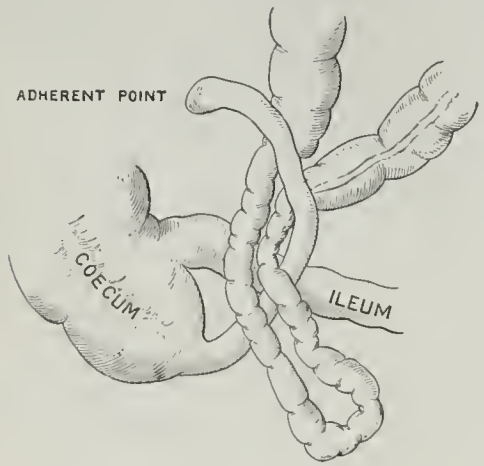

FIG. 1.—Strangulated intestine from an adherent appendix.

into the hospital, nor had she had prior to this time any symptoms that pointed toward appendical difficulty. Then pain was felt in the region of the groin, and this continued with moderate enlargement of the hernial swelling. Three days ago she had severe pains, which doubled her up and compelled her to go to bed. With this she had some nausea, but no vomiting nor fever. On examining her a swelling the size of a large walnut was recognized just below Poupart's ligament. It was moderately painful, irreducible, and gave a slight impulse on coughing. The abdomen was generally soft and *free from rigidity* and a little tender above the ligament, but not more so than is often felt in a strangulated hernia, which this was taken to be. Pulse, 128; respiration, 20; temperature, 101°.

At the operation, done immediately after the preceding examination, it was found, on exploring the sac by the usual vertical incision, that it was of a bluish-black appearance, suggestive of a congested or gangrenous intestine, but this proved to be incorrect, for on carefully incising the sac two or three drachms of rather dark serum escaped. On further enlarging this opening to see into the hernial sac, neither intestine nor omentum was found in it, and its neck was so much narrowed as barely to admit a probe. It was then evident that this small accumulation of fluid did not account for the tenderness in and above the tumor. A renewed palpation of the area of abdominal tenderness showed with the ether relaxation, running from the femoral ring upward under the rectus muscle, a deep resistance suggestive of a Littré hernia or a possible appendicitis. The abdomen was, accordingly, freely opened by the intermuscular separation method of McBurney, conjoined with the transverse division of the anterior and posterior layers of the sheath of the right rectus, which muscle was strongly drawn to the median line. This gave a large view of the entrance to the femoral canal, which was free from intestine or omentum, but blocked up by an enlarged gland pressing against it from under the peritoneum, and well toward the median line was felt an elongated, movable mass which turned out to be an inflamed, thickened appendix covered at its middle with a layer of fresh fibrinous exudate. The appendix was removed in the usual manner, cauterized, inverted, and secured by a purse-string suture, and the abdominal wound closed. The hernial sac was extirpated after ligation of its neck, and the femoral canal closed by the Bassini method. The appendix when incised showed its walls and its mesentery to be thickened and infiltrated with pus.

In this case, as well as in the preceding one, there was an absence of the rigidity of the abdominal wall, the presence of which is, with justice, looked upon as an evidence of peritoneal inflammation. In each case this membrane was, it is true, involved only to a moderate extent, and perhaps in the first case its invasion may have occurred at the period when the rigidity did develop. While rigidity may be occasionally absent and thus mislead the surgeon, the reverse may also occur, and we have to keep in mind that this symptom may be provoked by pneumonic and pleural inflammations and more rarely by grip or in the early stage of tetanus. Very lately an experience came to me in which, with high abdominal pain and abdominal rigidity, there was associated a temperature of 104° and rapid breathing, 52 per minute, and tympany nearly to the nipple level. The ear of an expert medical man detected amphoric tinkling and a double friction sound. It was here more dangerous to wait for probable chest developments than to resort to an exploratory incision. This done, revealed a perforated duodenal ulcer with gas and fluid extravasation between the liver and the diaphragm. The marked rigidity influenced me strongly in my intervention, in spite of the supposed pulmonary origin of his disease.

Furthermore, I would like to call attention to the fairly protective agency of the mesentery in this and in many of these appendical infections. It is true that this is only a temporary stay, but I have been struck with the frequent perforations of the appendix in this direction, and believe that it often sufficiently hinders the infectious action to allow of the limiting action of the exudate to be safely carried out. Six of the eleven specimens before you representing recent and consecutive appendicitis cases, which have been beautifully mounted by Dr. Carleton Flint, illustrate this point very well. It is well known that the various peritoneal fold, stretching from the small to the large intestine at the ileocolic valve, also aid in limiting an abscess in the region.

Strangulated Hernia with Gangrenous Appendix.—In operating for the cure of a right-sided hernia, it is not very rare to find the normal appendix in the sac. This has occurred to me a number of times, and I have once seen thickened and chronically inflamed appendix in the sac of a strangulated hernia. But in the case now to be narrated the hernia, which was but little strangulated, contained also a gangrenous appendix. The details of it were as follows: A woman aged sixty-seven years entered the Roosevelt Hospital on December 11, 1902, with the statement that a swelling appeared in her right groin a week ago, which gave her pain, and that this had persisted and increased. She had had no vomiting, and her bowels had moved daily. The tumor over the external abdominal ring was the size of a peach, soft, compressible and painful, and had a slight impulse on coughing. She had had no previous attacks of abdominal pain. The diagnosis was of strangulated or incarcerated hernia.

The operation was done at my request by my

assistant, Dr. Brewer. On opening the sac, which contained some two or three drachms of clear fluid and a slipped cæcum, a short gangrenous appendix was found. The bowel itself was but little congested, and the retaining constriction was but slight and did not require any section. The appendix at its base was flaked with lymph. It was ligated and cut off, its stump cauterized, disinfected, turned into the cæcum and held so by a purse-string suture. The cæcum itself was of the conical type. The hernial opening was closed by Bassini's method with a small cigarette drain to the stump of the appendix. Uncomplicated recovery.

I take it that the gangrene here was aided by the hernial constriction which, even though it was slight, probably compressed the blood supply of the appendix. While in women, in a certain percentage, there is an additional artery to this useless organ coming through the ovarian ligament, yet in either sex in a hernia, a slight pressure plus an infectious inflammation would be sufficient to produce a gangrene. It is not stated what the length of the mesentery was. This has been considered by some to be of moment, as it has been thought that gangrene was more apt to occur in those cases in which the mesentery reached half way down the appendix or less than this distance. Ochsner says that, on account of this anatomical point, gangrene is rarely complete above the middle of the appendix. The researches of Monk and Blake* of Boston, in nearly 700 autopsies, however, show that the mesentery extends the full length of the appendix in 64 per cent. of the cases, and that in only 6½ per cent. does it reach half way down. Certainly this is insufficient to allow us to count much on the influence of outside circulatory influences in the death of the appendical walls.

The next case is an interesting one of *cystic enlargement of the appendix*, which Dr. Brewer has kindly placed at my disposal.

A woman aged thirty-eight years, who had an ovarian cyst removed by a median laparotomy twelve years ago, and who five years ago underwent an operation for appendicitis at the hands of a gynecologist of this city and now deceased, and believed that there the appendix was removed. A ventral hernia resulted at the site of this operation, for which she wore a supporter. Ten weeks ago she began to have pain again in the right iliac fossa, which was at first ascribed to the rupture. The pain was of a dull aching character, varying in severity, and occasionally was sharp and darting through the hernia. Micturition also became frequent and urgent. When admitted to the Roosevelt Hospital on January 10, 1903, her temperature was normal, pulse 96°, respiration 24. On examination the right lower quadrant of the abdomen was seen to bulge unduly from the resulting paralysis of the rectus muscle following the previous operation. Through the stretched cicatrix could be felt an elongated swelling apparently five or six inches long, just outside the iliac artery and running forward toward the anterior brim of the pelvis. This mass was movable and very tender on pressure. It was supposed to be a small ovarian cyst. An incision by Dr. Brewer to the inner side of the former scar exposed, in the peritoneal cavity, after separating a number of adhesions, an enormously distended appendix 4½ inches long and over 1½ inches in diameter. (See Fig. 2.) At its cæcal origin there was found about an inch of normal sized appendix, which allowed its ligation, section, and inversion of the stump by the usual methods. Closure of the abdominal wound completed the operation. The patient made a prompt recovery. The distended appendix had thin walls and was translucent to ordinary light, and the fluid therein was of a clear yellow color. The specimen is be-

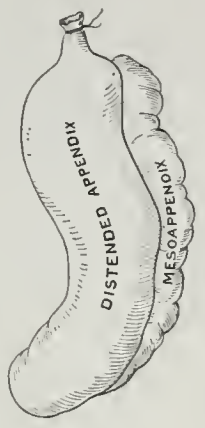

FIG. 2.—Cyst of appendix—4½ inches long and 1½ inches broad (Dr. Brewer's case.)

fore you, though it has somewhat shrunken in the fluid in which it has been immersed.

I have myself once encountered in an internal operation a cystic distension of the appendix, but of a less size than this.

Among the other queer things connected with our surgical benefactor, the appendix is an instance of a

Tumor of the Cæcal Wall Following the Removal of an Appendix.—The patient, a young woman of twenty years, underwent, in June, 1902, an internal operation for recurring attacks of appendical pain, but since that date there had been a continued soreness in that region, and three times since she had attacks of pain like those experienced before the operation and which were supposed to be appendicular in origin. With the last two attacks she had had vomiting, diarrhœa, and fever. The last of these attacks occurred only a week before her admission into the hospital on November 29, 1902. Her symptoms, which her last physician said were those of an acute appendicitis, continued three days, since when there has existed soreness over the region of the appendix with nausea after meals. There is, the record states, tenderness on deep pressure over the appendix and a small hard and sensitive mass with a greater vertical diameter can be felt directly underneath the cicatrix of the operation of June last.

Naturally Dr Brewer, in whose care the patient was, thought that there might be some error in the statement given him that the appendix had already been removed, but on writing to the surgeon who officiated at the operation and who is a man of good surgical training, it was learned that he had been reported correctly and that after removal of the appendix the stump had been inverted into the cæcum, as is customary. Dr. Brewer opened the abdomen and found no appendix, but at its site there was a small, hard tumor three-fourths of an inch in diameter, projecting externally and also into the lumen of the cæcum. It was excised and the resulting opening into the intestine and of the abdominal wall duly closed. The tumor on section presented a fibrous appearance and on microscopic examination by the hospital pathologist was pronounced a chronic inflammatory condition of the wall of the appendical stump.

Dr. Dawbarn several years ago called attention to the possibility of the stump of the ligated

*"The Normal Appendix, etc."—*Boston Medical and Surgical Journal*, November 27, 1902.

and excised appendix giving rise to subsequent trouble when inverted into the cæcum and covered over by the sutured peritoneum He reasoned that because the small portion of the infected mucous membrane between the cut end of the appendix and the ligature when thus closed over might beget abscess, thickening or other infection, and hence to guard against this mishap suggested and practised at one time the procedure of inverting the stump without previously ligating it, and then suturing over it the peritoneum, so that whatever inflammatory products might arise could thus readily be emptied into the cæcum. This was tried by myself and others and found to be not always safe, as in carrying out the suggestion there would at times be an escape of cæcal fluids from the open appendical tube which might infect the peritoneum. Moreover the procedures adopted to obviate these supposed risks, of which the above case is a good but a rare illustration, have been proved beyond doubt to be generally satisfactory. These are either to dissect away the diseased mucous membrane from the cut end of the appendix down to the ligature, or, what is easier and better still, to destroy the membrane by the small point of a Paquelin cautery. Some use efficaciously a cauterization of the same membrane by a swab of pure carbolic acid. So far in my experience, I have never seen any mishap follow such a treatment of the stump. In this individual case it seems that cauterization of the stump was not resorted to in any form.

As a contrast to the foregoing case, and yet allied to it in appearance at least, I beg to give you one in which *a very short appendix one-half inch long was productive of several sharp attacks of appendicitis.*

A gentleman, aged fifty-nine years, had several sharp attacks of appendicitis, one of which caught him away from home and decidedly imperilled his life. Though he had been assured by his physician (an able homœopath) that he could cure him, he was unwilling to risk further his life (a particularly valuable one in a business point of view), and therefore accepted operative treatment in a quiescent interval. The usual intermuscular separation operation was accordingly resorted to, but so many and so extensive adhesions were found that the section of the rectus sheath in front and behind, with retraction of the muscle (which Dr. Farrington of Boston, Fowler of Brooklyn and myself independently worked out as a good wrinkle), was employed to get a satisfactory exposure of the desired area. When this was accomplished the *fons et origo mali*, the appendix, was only found after some search, as it was hardly half an inch long and nearly the same in thickness. After its removal it was seen that its lumen was nearly obliterated and that its walls were very much thickened and sclerosed It was at first supposed that it was merely the remains of an appendix and that the major part had been destroyed in one of its severe attacks, but a renewed inspection showed it to be complete. His recovery was prompt and permanent.

One incident of this operation still remains vividly before me. As I began sewing up the abdominal wound, I said, according to my routine, to the assistant, "Have the abdominal pads counted," of which I only employ a fixed number. The nurse, told to do so, reported in a moment, "One is missing." "Count again and look around for it." Again the report, "One is missing." I had by that time the wound half closed. Nothing remained but to undo the entire line, insert my fingers first and then my hand to feel around for the missing pad. I could not find it. My thoughts ran rapidly that my disturbing his intestines was a damaging thing, but if the pad were there and I didn't find it then and did find it in an autopsy, what a position I would be in—for this was a case in which the reporter's zeal would find out the worst and exaggerate even that! After a while I stopped my examination and said, "It is not there." A final specific inquiry as to whether any one before the operation had touched my pile of a dozen pads, brought out the information from one of the nurses that she had need of a cover to some brandy and water in a tumbler and had cut off a piece from one of them and had put the end having the tape attached to it in her pocket. She was a fine nurse and hitherto of excellent record, but I then thought some hard things of her. One of the family physicians present also had his say about it afterward, and suggested a little sarcastically that "you surgeons ought to be more careful in your management of your pads," but when I asked his enlightenment as to improved methods I got no valuable hints from him.

This point of lost pads, instruments, etc., in laparotomy operations has been much ventilated lately, not only in the public prints concerning the resulting fatal mishap in the practice of a distinguished western surgeon, but also from a proper scientific standpoint in a paper on this subject by Dr. Schachner* of Louisville, Ky., who collected some 154 instances in which it had occurred, notwithstanding the many plans suggested to obviate this risk. The methods usually adopted by myself and the surgeons in this city and, I think, elsewhere, is to allow no pads or pieces of gauze to go into or remain in the abdominal cavity unless in the grasp of a forceps, or to which clamps have been attached. Usually tapes are sewn to the pads, which hang some distance outside the wound and to which clamps are fastened. As the handles of the clamps often catch the suture threads, etc., to obviate this nuisance I have substituted the ordinary harness ring, which is, beforehand, sewn to the outer edge of the tape and, with the pads, duly sterilized. These pads or gauze pieces should be counted before and after an operation. All drainage tubes are guarded by a large safety-pin, and if several pieces of gauze are introduced into a wound they are tied together by a ligature. If a single piece of gauze is used, I generally secure it by a suture to the skin. This "fussiness" has been induced by having had the ill luck to leave once a sponge in the abdominal cavity with a fatal result, and twice pads with the recovery of the pads and patient after a retention of the former for, respectively, two weeks and four months, thus showing a tolerance for pads beyond sponges, which fact has been noted by others. In each of these three operations I was helped by two able assistants, who have since developed into attending surgeons of the largest hospitals in this city, and who each reported at the time that all the sponges and pads were duly accounted for. Five times have I been called to extract sponges or pads from the abdominal cavity left there by other surgeons, most of whom were justly of eminence. I emphasize this because it shows that care must have been taken in every instance by such men, and hence the judgment given in the Western case in favor of the surgeon should be considered as a just and proper one. This surgical retention of a pad or drain in a wound is as much one of the recognized risks of an operation as is hemorrhage, intestinal damage, or infection.

This, I know, is somewhat of a digression, but, as I before said, it was a painful five minutes to me,

*Annals of Surgery, November, 1902.

and I believe most surgeons in large practice have met with this accident. More germane to the case are the facts gathered in the paper previously quoted of Monk and Blake in respect to the length of the appendix. While this one was and is the shortest I have yet encountered, and seven inches is the longest, these authors report from 641 autopsies that the shortest appendix met by them was a little over one-third of an inch in length, and the longest one measured a little more than nine and one-third inches, the average length being about three inches.

I hesitate a little in adding anything more to the rather discursive cases of this paper, but I venture to place one more on my list, not that it is unusual, but that it represents a treatment that is largely employed at the present time for several surgical conditions, and whose working is yet obscure to us. I refer to the use of saline infusion in septic conditions and in shock. The best explanation of the good effects in sepsis that is advanced is that it helps the kidneys, skin, and lungs, but particularly the first, to carry off the diluted toxins.

Appendicitis with General Peritonitis; Operation; Repeated Infusion; Recovery.—Man, thirty-two years old; admitted to Roosevelt Hospital on August 9, 1902, for appendicitis of three days' duration. Temperature, 102°; pulse, 104; respiration, 32. Entire abdomen rigid and very tender. No mass or localization of signs. Leucocytes, 34,000. Urine negative. Operation by Dr. Brewer. Kammerer incision. Appendix found gangrenous and ruptured. Free purulent fluid throughout abdominal cavity. Thorough irrigation, and wound closed with large drains going to pelvis and right iliac region.

August 11.—Frequent vomiting. Temperature, 106⅗°; pulse, 160 and weak. Urine scanty, fifteen ounces. Case considered hopeless by attending surgeon. The house surgeon, Dr. Geyer, asked permission to try infusions. One of 1,000 c.c. given at 5.30 P.M., and lavage.

August 12.—Temperature, 105⅘°. Three infusions and three lavages given during afternoon, each 1,000 c.c. Urine up to forty ounces passed, with drop of temperature to 101°.

August 13.—Again elevation of temperature to 104°. One infusion of 1,000 c.c., three saline enemata. Urine thirty ounces. Thence on, steady improvement and recovery.

In the use of the venous infusions of normal salt solutions, aside from an occasional chill and temperature elevation produced by them, and which is of a rather transitory nature, there are two objections likely to be encountered. One of these has been noticed by Crile and others, that when the fluid is injected into the circulation in large amounts saturation of the tissues or, technically, "wetting" takes place, which is shown by pulmonary hypersecretion and sometimes by a puffiness of the face with a watery-eyed appearance. When these appear one may assume that a similar condition exists elsewhere, and that the most dangerous of all, an œdema of the brain, may be produced. Therefore with us and with others, the amount injected is limited to about 1,000 to 1,250 c.c., repeating the same according to the diminution of the pulse tension.

A second objection, yet more than half theoretical, is that made by Lennander, that with a salt infusion there is not in the cells of the tissues and the blood fluids such an exchange of carbonic acid and oxygen as is normal, and at his suggestion, commended after trial by Arthur Barker of London, we have at the Roosevelt Hospital largely added to the salt-solution 5 per cent. of sterilized glucose or, which answers, as Schieking says,* the same purpose, 0.03 per cent. of the saccharate of sodium. It is difficult always to appreciate the value or results of any medication, but since I have employed this addition to the salt-solution I have found a rosier hue maintained or produced after the venous injections, and feel encouraged to continue its use. Furthermore, it has been felt that another suggestion of Crile, whose experiments in physiological surgery are so interesting and valuable, of adding to our salt infusions from 10 to 15 minims of a 1 to 1,000 solution of the adrenalin chloride has been productive of good results, and that the reaction obtained in the circulation is more lasting than from the ordinary saline fluid.

Cancer of the Appendix.—In conclusion I desire merely to place on record a rare instance of cancer of the appendix. Only fourteen have been collected since 1896 by Dr. Moschcowitz of this city. The interesting point is not only that the appendix should be involved in the neoplasmic invasion, but that in the few cases that have been traced for some time after the operation no recurrence has taken place. The following is an example of the good effect of a thorough removal of a growth in its early stage:

Man, twenty-three years old, was admitted to the New York Hospital on June 7, 1893, with history of thirteen attacks of appendical pain within two years. Nothing could be felt through the abdominal walls, nor was there anything special noticed in the appendix, which was strongly kinked and knobbed a little more than usual at its end. The stump was cauterized (a treatment used generally as early as this period), and the removed appendix sent unopened to the pathologist of the hospital, Dr. Ferguson, for examination. He reported, in addition to the usual inflammatory changes in the mucous membrane, that at the tip of the appendix there was found a small mass of adenocarcinoma.

The patient was kept under observation for over three years, during which time no recurrence took place; that is to say, he remained in good health. Since that time he has been out of my observation.

The case was briefly alluded to in the discussion on this subject in the Transactions of the American Surgical Association last year. This must have, from the chronology of Dr. Moschcowitz's collection, been the earliest recognized case of this complication.

I am open to criticism in not publishing it before this, but in medicine, as in poker, one generally wants a pair to open, and its fellow never came along.

With this exception and that of the short appendix, the foregoing list of odd and interesting cases of appendicitis have all occurred within the last year. Many others have been previously noted, but with the increased and increasing number of appendical cases that present themselves in every large hospital, a rare case is rapidly duplicated, and a special experience rapidly becomes generalized. This is hoped will follow from the present paper.

11 East Fifty-fourth Street.

Credentials for Scientists.—The State Departments, on May 2, issued special credentials to three well-known scientists who are going to Europe for the World's Fair Commission to insure the success of the Scientific Congress which is to be held in St. Louis. These are Simon Newcomb of Washington; Profs. Hugo Munsterberg of Harvard and Albion W. Small of the University of Chicago.

*"British Medical Journal," Epit., p. 20, 1900.

ON A CASE OF COMPLETE FIBROUS OBSTRUCTION (CONGENITAL?) OF BOTH SUPERIOR AND INFERIOR VENÆ CAVÆ IN A YOUNG MAN OF EIGHTEEN YEARS—FIRST RECORDED CASE.*

ALFRED MEYER, M.D.,
NEW YORK.

Enough cases of complete obstruction of *either* the vena cava superior *or* of the vena cava inferior alone have been published to rob cases of this kind of some of their interest. Thus Welch ("Allbutt's System," Volume VI, p. 217) reports 140 cases of obstruction of the inferior vena cava from thrombosis, without considering other causes of closure. Still every instance of this kind, independent of the question of rarity, is of great interest from the point of view of diagnosis, etiology, and the establishment of collateral circulation. But when this obstruction implicates both venæ cavæ, as in the case of which history and post-mortem follow, this interest is enhanced manifold. A very diligent search of the literature of all countries has failed to discover the report of another similar case. I believe, therefore, that it is the first case of the kind on record.†

The patient was a young man (H. S.), single, sewing-machine operator, aged eighteen years, admitted to Mount Sinai Hospital, September 16, 1902.

Family History.—Practically negative. Father, forty-seven years old, healthy; had married at age of twenty-two years and had never had any venereal disease. Mother, forty-seven years, healthy. There were seven children, of whom one had died at age of fourteen years of Asiatic cholera.

Previous History.—Had Asiatic cholera seven years ago; at the time his brother died of the same disease; also had measles. Four years ago was told by a physician that he had kidney disease and water in the abdomen. Otherwise negative; in particular no scarlet fever, diphtheria, pneumonia, typhoid, rheumatism, malaria, or jaundice. No venereal disease, no alcohol, no tobacco.

Present History.—One year ago began to have ulcers on legs. These healed after some time, but broke open again some months ago. Was able to work hard on a sewing machine until four weeks before his admission. Since that time his abdomen began to swell gradually, as did his left foot and scrotum. One week before his admission abdomen was tapped and three liters withdrawn. No headache, no eye symptoms. Urine high-colored; no cardiac symptoms. Cough and dyspnœa, which were relieved by the tapping previously alluded to. No vomiting nor anorexia. Bowels costive. No loss of weight.

Physical Examination. — *General Condition.*—Poorly nourished. Tongue moist and slightly coated. Teeth and gums in poor condition, but no Hutchinson's teeth. Mouth and throat otherwise negative. Skin dark and muddy, especially in axillæ. No icteric discoloration of conjunctiva. Numerous scratch marks on arms, face, neck, chest, and abdomen. Wound at site of paracentesis abdominis. Anterior and posterior cervical glands enlarged; also axillary glands and glands leading from right axilla to right breast. Slight enlargement of epitrochlear glands and marked enlargement of inguinal glands. Two large ulcers on the anterior surface of left leg, one on right leg with foul discharge. Signs of numerous smaller healed ulcers. Small scars on posterior surface of neck; numerous scars on scalp. Marked dilatation of the veins of the chest and side of the abdomen, also of lower abdominal veins. Some dilatation of the veins of the neck and back and of both upper and lower extremities.

Lungs: Anteriorly.—Some dulness lower part of right and left axillæ. Slight dulness behind upper part of sternum and at left apex.

Posteriorly.—Dulness left apex and interscapular region. Some dulness both bases. Otherwise negative.

Heart.—Right border just outside of sternum. Left border just outside of nipple line. Action slow, regular, faint aortic sound. No murmurs. Apex beat fifth space, inside the nipple line(?). Pulses equal. Slight thickening of arteries(?). No tension.

Liver: Upper Border.—6th rib mammary line. 6th space axillary line.

Lower Border.—5.5 cm. below free border ribs mammary line; 5 cm. below free border ribs axillary line; 6 cm. from tip of ensiform, midsternal line. Surface smooth, edge sharp, hard.

Spleen.—Seventh rib, two fingers in front of the anterior axillary line. Palpable two fingers below free border of ribs. Edge hard and sharp.

Abdomen.—Lax, tympanitic in center, dull at flanks, change of note on change of position. Circumference of abdomen 81 cm.

Extremities.—Some œdema and cyanosis of feet.

Blood Examination.—Red, 4,550,000; white, 6,000; hæmoglobin, 70 per cent. Blood spread negative.

Urine.—Acid, 1,024; albumin trace, no sugar, 2.2 per cent. urea, micr. neg. Temperature on admission slightly above normal. Pulse 106, respiration 26. The patient was at once placed upon xv gr. doses of sod. iodide, t. i. d., and mercurial inunctions ss. oz. q. d., by Dr. H. W. Berg, adjunct physician.

Subsequent History.—Patient was first seen by me on October 11, 1902. The absence of any visible apex beat was noted, with normal cardiac dimensions, and pure, though somewhat distant, heart sounds. A presumptive diagnosis of total pericardial adhesion was made, although confirmatory evidence in the shape of pulsus paradoxus was looked for in vain, and there was, of course, in the absence of any apex beat, no systolic retraction. Still this diagnosis seemed best to explain the obstruction to the circulation in both the upper and lower halves of the body, with the attendant enlargement of the superficial veins, the cyanosis, the œdema, the ascites, the enlargement of liver and spleen and the ulcers on the lower extremities. For, in the absence of valvular lesion, total pericardial adhesion has been found repeatedly without any hypertrophy of the heart, and when present in children has even led to some atrophy of that organ. (Allbutt, "System of Medicine, Vol. VI, p. 786). The widespread enlargement of the lymphatic glands, it was thought, could be explained in one of three ways, none of which was incompatible with the diagnosis of total pericardial adhesion (1) because of backward pressure in the thoracic duct in the absence of free anastomosis with the right lymphatic duct, as described in thrombosis of left innominate vein, by Ormerod and Sydney Martin (Allbutt, *loc. cit.*, p. 443); (2) because of a possible syphilis, which might be at the same time the underlying cause for the presumptive total pericardial adhesion; (3) because of the cachectic state of the patient.

There was a gradual increase in size of the abdo-

* Read before the Medical Section of the New York Academy of Medicine, April 21, 1903.

† Cayley published a case under the misleading title of "Obstruction of Both Venæ Cavæ," in Middlesex Hospital Report, '01, Lond., '02, page 61, which appears to have been merely a case of simple mitral stenosis and insufficiency with failing compensation, and therefore need not be considered further.

men in spite of rest in bed and the use of digitalis, so that on November 7 the circumference equaled 87.5 cm.

Taken during life, showing enlargement of veins in inguinal and latero-abdominal regions.

November 30: Abdomen was tapped, and over three quarts of turbid, yellow fluid were withdrawn. The fluid presented the following characteristics: Specific gravity 1011, alk., no sugar, no bile, no urea, no iodine (in spite of large amounts of NaI taken).

Alb., 1.5 per cent. Did not clear upon shaking with ether. Microscopic: An occasional fat globule, a few red blood cells.

December 1: Slight icteric discoloration of conjunctivæ. Circumference of abdomen, 79.5 cm. Ulceration on extremities healed.

December 12: Circumference 85 cm.

January 7, 1903: Temperature arose suddenly to 104.8°. Somewhat more cyanotic.

January 8: Fever ranges between 101 and 103.6°. Complains of sore throat. A few patches of exudate visible on tonsil and pharynx. Throat culture: Negative.

January 9: Feeling better. Temperature 100–102°.

January 10: This evening temperature again arose to 104.8°.

January 11, A.M.: Complains of pain in right leg. On inner surface of right thigh is a red and painful area, 4x6 inches, that is tender, sharply defined, not indurated. Right inguinal glands much enlarged and tender. Indications of lymphangitis extending between inflammatory area and groin. Temperature at 11 A.M., 107.2°, when he was removed to isolation house for erysipelas, in a very feeble condition with a pulse of 170. A pale red area extended then as far as the umbilicus. Vigorous stimulation and antipyretic treatment reduced his temperature to 104° and pulse to 140. He also received 20 c.c. of antistreptococcic serum.

January 13: Erysipelatous redness has extended down to ankle over sacrum and left trochanter. Periods of delirium. Septic odor of breath. Marked cyanosis of face and hands. Fever between 104 and 105°.

January 14: Death at 8 A.M.

Post-mortem by Dr. E. Libman, Assistant Pathologist, five hours after death, through abdominal incision. Marked rigor mortis, œdema of both extremities, of slight degree. Pigmentation both legs anteriorly. General icterus. Body fairly well nourished. General glandular enlargements (as described in clinical history). Dark red infiltrated area at right thigh extending up over abdomen to umbilicus. Ears dark blue in color. Small hemorrhagic area at posterior margin of auricles. Veins of abdominal wall distended and very prominent. This is particularly true of lateral veins.

Abdomen.—Adhesions between abdominal wall and liver. Large amount of bile-stained fluid in abdomen. Spleen adherent to abdominal parietes, rotated so that it lies transversely with lateral surface anterior.

Thymus.—Small.

Lungs.—Right: Large amount of bile-stained fluid in pleura. Lung compressed. Congestion of lung. Slight œdema.

Left: Markedly adherent, sacculation of fluid at base between diaphragm and lung. Parenchyma as in right lung.

Pulmonary Vessels and Bronchi.—Negative.

Bronchial and Mediastinal Nodes.—Bronchial nodes all enlarged, pigmented, some soft, others quite firm. Most are grayish in color. Size up to about that of lima beans. Mediastinal nodes same, only slightly pigmented. In a few bronchial nodes, some tubercles are present.

Heart.—Moderate increase of fluid in pericardium. No adhesions. Heart rather small. Cavities not enlarged. Slight thickening of free edge of mitral and aortic flaps. Some thickening of endocardium between aortic and mitral valves. Heart muscle cloudy, brownish. Coronaries and aorta negative. No congenital lesions.

Measurements and Weights.—Heart weighs 210 grams. Length of left ventricle, 8.5 cm. Tricuspid ring, 12 cm. in circumference. Mitral ring, 9 cm. in circumference. Pulmonary, 5.5 cm. in circumference. Aortic, 6.5 cm. in circumference. Diameter of coronary sinus, 0.5 cm. Arch of aorta, 4.5 cm. in circumference. Thoracic aorta, 4.0 cm. in circumference.

Spleen.—Very large, firm, adherent to parietes. On section, marked congestion. Malpighian bodies enlarged. Increase of connective tissue. Measures 9.5x14.0x18 cm. Weight, 1,000 gms. (29 oz.).

Kidneys.—Somewhat enlarged. Weight together 420 gms. (14 oz.). Capsule slightly adherent. On section quite firm, cloudy, quite marked congestion of parenchyma and injection of vessels of surface.

Adrenals.—Right: Embedded in and compressed by a mass of connective tissue on under surface of liver. Adrenal very flat, dark brown in color. No differentiation between medulla and cortex.

Left: Small, dark brown in color.

Liver.—Very much enlarged. Extends to umbilicus. Quite firm and adhesions to parietes. Marked perihepatitis on lower surface of right lobe, especially about transverse fissure. Surface of right lobe anteriorly very granular. As a whole, the surface of the liver is quite irregular, with a slight tendency toward lobulation. There is a marked perihepatitis on upper surfaces. On section, liver quite firm, brownish in color, surface looks rather spongy. Branches of hepatic veins enlarged. Central veins all enlarged.

Measurements.—Weight, 2.36 kilos (5 lbs. 1 oz.) Width, 25 cm. Length of right lobe, 19 cm. Length of left lobe, 14 cm. Thickness (right lobe), 9.5 cm. Lymph nodes about transverse fissures much enlarged, dark reddish gray in color. Ductus venosus obliterated.

Portal Vein.—Does not appear to be much com-

pressed by the adhesions or nodes—circumference of vein 2 cm.

Gall-bladder.—Cystic duct completely stenosed by adhesions. Gall-bladder very small. Wall thick, whitish; pale mucoid fluid in gall-bladder, very pale yellow in color. Common duct rather narrow (but no stenosis at or near papilla). Hepatic ducts rather large. Hepatic veins, diameter of each 1 cm.

Pancreas.—Very firm; ducts not obstructed.

Stomach.—Moderately dilated. Mucosa swollen. Hemorrhagic areas—especially near pylorus.

Intestines.—Practically negative. Veins are moderately enlarged.

Mesenteric Nodes.—Very large, most size of lima beans, most are pale, some dark reddish in color. There seems to be quite some thickening of the mesentery and the various mesocolons.

Prostate and Bladder.—Negative.

Head.—Not opened.

Cavæ.—Superior cava ends at a distance of 6 cm. above auricle. Its circumference 3 cm. Near the termination of the cava, the wall is somewhat thickened. On the left side near the stenosis (about 1 cm. below it) is a small irregular tab on the wall. Above the atresia, for a distance of $\frac{1}{6}$ cm., there is only some fibrous tissue in which both innominate veins end. They are both small, the left being the smaller. The walls are quite thick. The right has a valve. There is no evidence of any inflammatory process at or near the atresia of the cava. The vena azygos major quite large, opens into the cava at the usual location, its circumference is 2 cm. There is a valve near its point of entrance.

Inferior Cava.—Shows atresia at the diaphragm, there is fibrous tissue about 1 or $1\frac{1}{2}$ cm. thick about its termination. The upper end of the cava is rather conical, the wall quite thickened, the atresic part is surrounded by the area of perihepatitis on the upper surface of the liver (but the vein does not appear to be affected by the perihepatitis). Circumference of inferior cava at widest part (behind liver), 4 cm.

Microscopic Examination by Dr. F. S. Mandlebaum, pathologist.

Lung.—Moderate amount of fibrinous exudate on pleura. Intense acute congestion, with numerous hemorrhages into lung tissue. Moderate œdema. Moderate anthracosis.

Heart.—Parenchymatous degeneration. Brown atrophy.

Pancreas.—Chronic interstitial inflammation. Islands of Langerhans not involved.

Spleen.—Intense acute congestion with hemorrhage. A few small areas of purulent inflammation. Gram's stain shows streptococci in these areas.

Kidney.—Intense acute congestion with hemorrhages. Moderate increase in amount of interstitial connective tissues. Slight cloudy swelling.

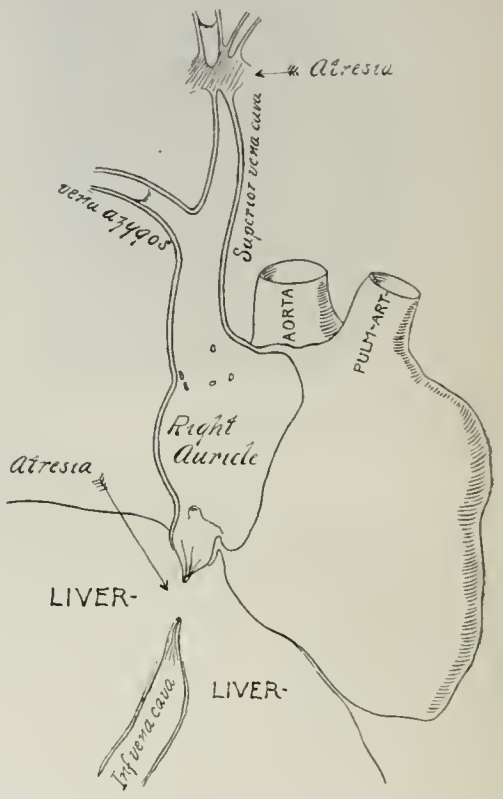
Adrenal.—Intense acute congestion with hemorrhage. Slight increase in interstitial connective tissue of cortex.

Liver.—Chronic congestion. Acute congestion with hemorrhage. Blood pigment. Perihepatitis. Large amount of connective tissue surrounds inferior vena cava.

Mediastinal Nodes.—Chronic interstitial inflammation. Acute congestion.

Mesenteric Nodes.—Shows similar changes, also a pronounced dilatation of the lymphatic vessels.

Epicrisis.—If this case is studied in the light of the post-mortem evidence, it is at once apparent that the entire return circulation was provided for by the dilated vena azygos major. Under these circumstances the amount of distention of the superficial veins during life, particularly in the territory drained by the superior vena cava, was strikingly little; in fact, much less than has been repeatedly observed in closure of one of these great trunks alone. This may possibly have been due to the gradual and slow manner of closure of these vessels permitting a great deal of time for the establishment of the deep and superficial collateral circulation. In fact, a rapid obliteration of either superior or inferior vena cava as by a thrombus, probably leads to a rapid death; and this result is in conformity with the results of animal experiment. Picard (*Comptes rend. des Acad. des Sciences*, Paris, '80, XC, p. 100) tied the inferior vena cava in animals, above the liver, and they all died within one-half to four hours,



with increasing frequency and diminishing force of the systole—the animals practically bleeding to death into the vessels below the diaphragm. (See also *Gazette des Hôpitaux*, Paris, '80, LIII, p. 99.)

In a study of the subject, Eppinger says (*Prager medicinische Wochenschrift*, '76, I, 725) that obliteration of the superior vena cava is almost always found just below the entrance of vena azygos. This is not so in my case—in fact, had it been so, it would have been incompatible with life.

The relatively lesser distention of the veins of the upper one-half of the body in my case must be explained by the fact that the return circulation is here not against the force of gravity, because mainly directed downward toward the heart, while the reverse is the case in obstruction of inferior vena cava; and in the latter case the circulation is in part contrary to the direction of the normal circulation. This difference in closure of the two veins respectively, has already been alluded to by Eppinger (*loc. cit.*), though he did not have an opportunity of observing the effect of closure of both of these vessels in one subject.

On the other hand there are recorded a number of cases of complete closure of inferior vena cava without any enlargement of superficial veins. Thus Andrew ("Transactions of Pathological Society," London, 1864-1865, XVI, 92) reports the case of a woman aged thirty-five years who died at St. Bartholemew's Hospital of epithelioma cerv. uter. and amyl. degen. of spleen, liver, kidney. The

inferior vena cava was closed for about an inch from a point just below the entrance of right renal vein by an organized clot which converted the vein into a fibrous cord. She had had an attack of dropsy ten months before death,from which she had recovered. Feet were swollen last two months of life, *but there was no enlargement of superficial veins.* Bloch (Über Obliter. der V. C. Infer., Jena, 1880) quotes a case from Ziemssen's "Handbuch der spec. Path.," in which there was a cicatricial obstruction of inferior vena cava below renal veins, with no distinct symptoms. Griffith (*Scalpel*, London, 1899, IV, 13), in a man who died at age of fifty-five years, found inferior vena cava completely closed just above renals, *i. e.* at a point between them and the hepatic veins. *No superficial veins enlarged*, no evidence of obstruction, and the man died of other causes.

Late Appearance of Large Veins in Obstruction of Inferior Vena Cava.—Cavasse *Bullet. Soc. Anat. de Paris*, 1897, LXXII, 811) found a probably congenital atresia of inferior vena cava at a point below renal vein, where the inferior vena cava ended in a filiform extension in a man dead of pneumonia at the age of fifty-four years. Enlargement of veins on the abdomen and blue spots only appeared two years before death.

Closure of Superior Vena Cava; No Evidence of Obstruction.—Banti (*Sperim. Mem. Orig. Firenze*, 1891, XLV. 408) describes a man who died at the age of forty-six years of acute miliary tuberculosis in whom the superior vena cava was converted into a hard and resistent cylinder 5.6 cm. in circumference, and there was no evidence of stasis in head, neck or upper extremities. In the majority of cases, however, closure of either of these vessels leads to enlargement of superficial veins, without whose presence the underlying condition would scarcely be suspected, much less diagnosticated. Thus Claverie (Reflex. sur cas d'oblit. du Veine Cave Sup., Paris, 1858) describes the case of a man who died at the age of fifty-two years, in whom the superior vena cava was converted into a fibrous cord for a distance of 1½ cm. at a point below entry of azygos vein; in addition there was a total pericardial adhesion. The patient had had great varicosities on the sternum, and from the axilla to Scarpa's triangle for thirty years.

Albuminuria.—Welch says that in thrombosis of the inferior vena cava albuminous, bloody urine is more often lacking than present. This is an interesting fact. In my case there was persistent absence of albumin, and of other evidence of congestion of the kidneys, until a few days before death, and then it was undoubtedly due to the fatal complication. Bloch (*loc. cit.*) reports the case of a man fifty-five years old, in whom he found a thrombosis of the external iliac veins and both common iliac veins and of inferior vena cava up to 40 mm. from foramen quadrilaterum (*i. e.* far above entry of renal veins), and in whom there had been no albuminuria.

Prognosis.—During a considerable part of last century the prevailing notion was that closure of the main vein of an extremity meant the gangrene of that extremity. Hence it is not surprising to note that in 1826 a professor of surgery in France ligated the femoral artery for a wound of the femoral vein, not daring to risk (as he thought) a gangrene of the lower extremity by ligating the wounded vein. In 1858 Claverie (*loc. cit.*) combated this view as erroneous, citing anatomical facts from the cadaver, results of surgical experience and of animal experiments against it. Still many able surgeons continued to be guided by the earlier theory until the end of the nineteenth century. A case like the present one illustrates strikingly how excessive have been these fears of gangrene, and how wonderful are the provisions for collateral circulation. Leaving out of consideration at this point the question of the probable congenital origin of the trouble, we have in the boy's history excellent proof of at least a four years' duration before his death, for he had been told by a physician at that time that he had kidney disease and *water in the abdomen*, and the nearest approach to gangrene subsequently were the ulcers on the legs referred to in the history one year before admission, and even they had healed repeatedly. As it is, the boy's death was finally due to erysipelas, a cause only indirectly connected with the obstructed vena cava (infected puncture wound), and, barring this occurrence, his condition at the time warranted the belief that he had many more months to live.

Claverie's case of obliteration of the superior vena cava already referred to lasted at least thirty years. In this connection it is interesting to note that the capacity of the veins to that of the arteries of the body is variously estimated. Borelli gives 4 to 1, Sauvages 9 to 4, Haller 2 to 1, and Sappey 2 to 1. Even taking the most conservative estimate as the correct one, this fact is of enormous advantage in overcoming the effects of occlusion of a large vein like either vena cava.

Collateral Circulation.—W. Thomas has perhaps made the most complete study of both the superficial and deep routes connecting the superior and inferior venæ cavæ and available in obstruction of either, or, as in my case, of both. (Beitrag zur Differentialdiagnose zwischen Verschluss der Pfortader und der unteren Hohlader. Bibliotheca Med. D., No. 2.)

In my case the *superficial* route was probably as follows: (*a*) Vena cava inferior, vena iliaca commun. or vena femoralis, vena circumflex ilei tegument, truncus anastamot. lumbo-vertebralis, sinus vertebralis externi, vena azygos, vena cava superior. The *deep* route probably as follows: (*l*) Vena cava inferior, either direct or via vena hypogastrica, to vena lumbalis ascend; vena azygos, vena cava superior. (*c*) Vena cava inferior, vena renalis (dextr. or sin.), vertebral sinus, vena hemiazygos (or azygos), vena cava superior.

Route "b" has been demonstrated experimentally by Schwartz and Walther (quoted by Thomas, *loc. cit.*). After ligature of inferior vena cava in animals they have succeeded in forcing foreign bodies by this route from the common iliac vein into the right auricle.

The picture of the patient taken during life shows not only the ascitic distention of the abdomen, but especially the enlarged veins in the latero-abdominal area. It has been found repeatedly that enlargement of veins in this area rather speaks for obstruction in the inferior vena cava, while when the enlargement is mainly present on the anterior abdominal wall and about the umbilicus the probability is in favor of obstruction in the portal system. My case supports the correctness of the generally accepted view.

Etiology.—In the larger number of cases the closure of the venæ cavæ is due to thrombosis extending into them from tributary veins (as after typhoid in inferior vena cava) and from pressure of various kinds of tumors (aneurysms, new growths, lymphadenomatous, and tuberculous glands). Still there have been published a large number of cases of atresia of the vena cava, the etiology of which has been obscure. In a few cases the authors have believed syphilis to be the etiological factor. A process of this nature might have been the cause of

the atresia of the vena cava in my case, in which the inflammatory adhesion to the liver presented at first sight the appearance of a healed gumma. On the other hand the atresia of the superior vena cava was not at all suggestive of such an etiology, and it is reasonable to look for a common cause for both. In addition there was no clinical evidence of either acquired or congenital syphilis in the boy, nor in his father; nor was there other evidence of either recent or old syphilis disclosed by the post-mortem examination; the ulcers, scars and even large lymph nodes being due to the severe chronic congestion. It is of course possible, but not probable, that one of the lesions was congenital and the other not. In the case published by Eppinger (*loc. cit.*) the condition and localization in the inferior vena cava resembled very closely that of my own case. At a distance of 21 mm. from the auricle the inferior vena cava came to a point and was then closed for a distance of 7 mm. and converted into a cord of the thickness of a quill; below the closure a gradual enlargement of the vessel, and its walls were united to a hepatic scar. He reached the conclusion that it was: (1) A syphilitic hepatitis, with development of scar tissue; (2) Involvement of the inferior vena cava in the scar tissue, then (3) Cicatricial occlusion of the inferior vena cava He also quotes a case reported by Klebs ("Handbuch der path. Anat.," p. 447) of a boy twelve years of age, in whom hereditary syphilis was demonstrated, including fresh syphilitic deposits in the liver and an obstruction (partial) of the inferior vena cava by scar tissue emanating from a gumma at the identical situation in the vein as in Eppinger's case. If lues were the etiological factor in my case he would put it in the same category as the cases of endophlebitis obliterans of the hepatic vein (supposedly due to syphilis) described in recent years by Chiari (*Beiträge zur pathologischen Anatomie*, Band XXVI), Churton and Lazarus Barlow (Transactions of Pathological Society, London, 1899), Kelynack (*Medical Press and Circular*, Vol. CXV, 1897), and Lichtenstern (*Prager medicinische Wochenschrift*, 1900, XXV, 325).

Jastrowitz (*Deutsche medicinische Wochenschrift*. Berlin, 1883, IX, 682) published a case of thrombosis of the portal vein of syphilitic origin. There was a whitish yellow gumma about the size of a walnut projecting into the portal vein, from which the thrombosis started, and there was a syphilitic cicatrix in the liver. Schueppel (Ziemssen's "Cycl. Pract. of Med.," Vol. VI, p. 493) reported three cases in new-born children of gummy peripylephlebitis, affecting either the trunk of the portal vein or of one of its main branches, the vein being changed into a thick dense cord with a much-contracted lumen. One case lived eight and a half days, another only eight hours.

In other cases the authors have believed a phlebitis (either exomeso- or endo-) to have been the cause, without assigning a syphilitic or other basis for the phlebitis. That there may be marked phlebitis without closure of the vein has been shown by de Giovanni (*Wiener klinische Wochenschrift*, 1893, VI, 578), and sometimes accompanied by marked hypertrophy of the muscular coat. In one case this hypertrophy was so marked that the vena cava was with difficulty distinguished from the œsophagus.

As curiosities I would mention a case reported by Thompson (Transactions of Clinical Society, Vil., VIII, p. 19), in which a needle, which had probably been swallowed, was the cause of a thrombosis of the inferior vena cava; and another by Peacock (Lond. Med. Chir. Tr., 1845) of a man sixty-eight years old, in which the lower two-thirds of the inferior vena cava was closed by a calcareous concretion extending into the right and left iliac veins. Banti (*loc. cit.*) reports the closure of the superior vena cava by a tuberculous endophlebitis.

In conclusion, I would state that Hirtz and Henniquin (*Bulletin Médical*, Paris, 1901, XV, 389) have attempted to show that there exists in certain families a veritable "arthritisme veineux," a "héridité veineuse," or a "phlébite familiale," an hereditary disposition to phlebitis and other venous affections. An investigation shows that nothing of this kind could be asserted of the family to which this boy belonged.

TOTAL RESPIRATORY FAILURE FROM ETHER—ARTIFICIAL RESPIRATION FOR OVER FOUR HOURS; RECOVERY.

By H. H. EVERETT, M.D.,
LINCOLN, NEB.

Mr. F. H., aged twenty years, a travelling salesman, came into the sanitarium with a history of a four days' illness, and presenting the following symptoms: Pulse, 110; temperature, 103°; abdomen, somewhat distended, tender over its entire extent, and very tender in the region of and below the umbilicus, where there was to be felt a thickened and very sensitive mass. He was nauseated, and presented a very unfavorable appearance. A diagnosis of acute appendicitis was made, and he was prepared for immediate operation.

In this case there was a clear history of a previous attack fourteen years ago, which followed one week after a fall from a coal-shed where he was playing. He had what was then called "acute peritonitis." He was desperately ill for six weeks, when he slowly convalesced. Since his early attack he has been entirely well, except for some constipation. Two years ago he had typhoid fever, after which his constipation increased.

His present attack began with vomiting, severe pain in the abdomen, centrally localized. The pain and abdominal tenderness increased, temperature and pulse mounting rapidly. The ice-bag was applied, salts and calomel and high enemas given, the symptoms slowly abating until, on the third day, he was so well that he expected to go to work the day following. That evening he became extremely ill, was very nauseated, vomiting frequently. His pulse and temperature again rapidly rose and his pains were so severe that his physician, Dr. H. J. Winnett, was forced to give him ¼ gr. of morphine.

The next day Dr. Winnett brought him into the sanitarium for operation. At the beginning of the operation his pulse was 130, temperature 103°.

An incision was made in the median line directly over the tumor mass. Free pus was found immediately on opening the abdomen. The intestines were highly injected and covered with a plastic exudate in many places. They were not overdistended with gas. The appendix was found to the left of the cæcum, firmly adherent. The whole mass, appendix, cæcum, and all lay almost in the median line, thus justifying the median incision. The appendix was firmly bound down and could not be brought up into the field of operation. It was gangrenous almost in its entire extent and contained a large fecal concretion. The peritoneal coat was split up and the diseased mucosæ and muscularis separated from their covering and removed. The stump was ligated because the surrounding tissues were so thickened and friable that it could not be inverted. The entire abdomen was now flushed with normal salt-solution, as is our practice in these

cases, it being impossible to wipe out all, or any considerable amount of the pus.

At this time was first noticed any indication of respiratory embarrassment. The flushing of the abdomen with hot salt-solution always produces a deepening and quickening of the respiration, but in this case it did not. Ether was now discontinued and $\frac{1}{30}$ gr. of strychnine ordered hypodermically, together with 30 minims of adrenalin chloride by mouth. The respirations became progressively slower and slower, until finally, ten minutes after the first untoward symptoms were noticed, respiration ceased. The pulse, just before the adrenalin chloride was given was 120 and of poor character.

Artificial respiration was instituted, the cyanosis, which was very pronounced, became gradually less until the skin was of an apparently normal color. The pulse from 120 slowed to 96, where it remained until the patient was returned to bed. Artificial respiraton was continued for four hours and twenty minutes before the slightest sign of returning respiration became apparent, and for thirty minutes after the first returning gasp it was continued, decreasing the force of the movements, as those of the patient became stronger and stronger.

During the four hours and twenty minutes of respiratory paralysis many expedients were tried. Strychnine was given to the amount of $\frac{1}{15}$ gr., atropine sulph., $\frac{1}{30}$ gr. in two doses of $\frac{1}{60}$ each at an interval of an hour, adrenalin chloride after the first and second doses of 30 minims each was repeated in 10-minim doses every hour. By rectum nearly 200 c.c. of normal salt-solution and whiskey were given, later 200 c.c. of hot black coffee. Both enemas were retained and absorbed. Lingual traction was tried faithfully, but, even in connection with artificial respiration, seemed of no benefit, only impeding respiratory efforts. Faradism was also valueless, and when applied caused contraction only of the muscles to which it was applied, impeding respiration instead of aiding. Flagellation proved useless, as did also any and all cutaneous stimulation. A mustard plaster was applied over the chest and produced a thorough reddening of the skin. Any irritation of the skin produced a reddening. Dilatation of the sphincter was several times resorted to, and in each instance produced a strongly marked stiffening of the entire body, every muscle seemingly on an intense strain. No effect was apparent on respiration except to impede it and produce a profound cyanosis. The pupilary reflexes were abolished; together with the conjunctival, these did not appear until the respirations reappeared. The pupil remained contracted throughout. This was so unusual that it was feared that morphine had been given instead of strychnine. This was disproved. The atropine had no effect upon the pupils.

To recapitulate, the only things which seemed to be of great service were artificial respiration and the adrenalin chloride.

Discontinuance of artificial respiration always produced cyanosis. Renewed efforts produced a pinkening of the skin and a return to a normal color. If it had not been for the active and laboring efforts of those at work, nothing unusual could have been detected in the appearance of the patient.

To the adrenalin chloride I think must belong the greater part of the credit of resuscitation. To it must surely belong the credit of the extraordinary slowing of the heart to nearly normal, and the remarkable increase in force and volume. At no time after the first dose of 30 minims did the action of the heart cause any anxiety.

To the atropine in a small degree, and to the salt-solution in a greater, was the elimination of the ether due, outside of the great amount eliminated by the lungs.

The intravenous injection of normal-salt might possibly have been of some value, but it was not done on account of the amount left in the abdomen and the amount retained in the rectum.

The ether was given in the most painstaking manner by our anæsthetist, who is one of the most careful in method. The ether was administered slowly by means of an Allis inhaler, and less than 100 c.c. was given throughout.

To Dr. Winnett and the several others present for aid in performing the artificial respiration great thanks are due, for it would have been almost impossible to have continued the respiration over such a length of time unaided.

Mr. H.'s respirations after leaving the table were thirteen only, but gradually rose to twenty, where they remained for some hours, they now slowly increased to twenty-six, remaining there for several days, and then as gradually dropping to normal, where they have been ever since. His temperature was at its highest the next day after his operation, when it stood 100.2°, but for this exception the temperature has been practically normal, ranging between 98.6° and 99.3 or 4. His pulse has never been over 100, and is now 76.

The adrenalin chloride was administered for a day after his operation, in doses of 10 drops every two hours. The administration of the adrenalin was not an untried procedure, as in several cases of cardiac failure from shock and hemorrhage it has been invaluable. I give it credit for saving life when I am sure without it the patient would have died. Our favorable experience with the drug dates from its introduction, and for that reason Dr. Criles' experiments gave us added confidence in its use.

His recovery is all the more remarkable when one considers the amount of manipulation necessary to continue respiration and the condition found on opening the abdomen.

Now, six weeks after his operation, Mr. H. is about town and is almost able to attend to his business.

Fabricated Cable Reports.—One of our contemporaries with a zeal worthy of a better cause, prints an alleged cable report of the proceedings of the International Medical Congress, in which there is so much internal evidence of fabrication that we are impelled to protest against the imposition in the interest of truth and fair play. There does not appear in it a single item that could not have been obtained before the meeting was held, and even the few that are offered either lack directness of statement or are not correctly presented as regards actual occurrences. Altogether it reads like a sensationally worded newspaper report in the effort to make something out of nothing. This is certainly not fair to the readers of a strictly scientific periodical. How it could have been possible, for instance, to have cabled the following it is difficult to conjecture: "An expedition to the Escurial and another to Toledo formed part of the social festivities among which (by no means the least) was a bull fight given especially for the edification of the members of the Congress." No such entertainments took place, as witness the following cablegram to the MEDICAL RECORD as part of its report received direct from Madrid: "April 28: No bull-fight. Excursions to Toledo and Escurial not given by Congress."

When our proceedings of the sections are published as taken on the ground by our representative, there may be other opportunities for comparing notes as to what actually did occur even at the specially selected section meeting in question.

A NEW FACTOR IN THE ETIOLOGY OF MALARIAL FEVER INDICATING NEW METHODS OF TREATMENT.

DR. A. F. A. KING of Washington published a paper with this title in the *American Journal of the Medical Sciences*, February, 1902. He thinks that since malarial fever has been proved to be a parasitic affection, of which the paroxysms are produced by sporulation of successive groups of parasites in the blood, it behooves us to reconsider some of our former ideas as to the influence of meteorological factors in the etiology of the disease. Solar heat has long been regarded as of the first importance in the causation of malarial fever, but the writer argues that there seems to be no scientific evidence that the heat of the sun is in any way an etiological factor, and he would explain the undeniable relation between hot climates and malarial fever, by eliminating the term "heat" and substituting that of "light." Dr. King, therefore, proposes, as a working hypothesis, that it is the light of the sun, not its heat, that determines the periodic sporulation of parasites in the blood, and he puts forward the evidence in support of this theory in the following statements: (1) The accumulated experience and observations of centuries, which have been held to prove the agency of solar heat in causing malarial fever, may be held to prove the agency of solar light. (2) Paroxysms of intermittent fever will not, as a rule, take place at night in the dark. (3) The relative liability and relative immunity of different races of men to malarial fever depend upon the relative translucency or non-translucency of their skin, and probably of their blood. (4) In places where malarial fever prevails the disease is increased by bright, sunny weather and lessened by clouded skies. (5) It has long been a popular tradition that to prevent the occurrence of ague, or to forestall its recurrence when it has once occurred, it is advisable to keep in the shade and to avoid sunlight. (6) The malarial parasite is a naked amœba. Red light promotes the vital activities of amœba, while violet or purple light restricts them. The color of the light diffused through the blood is necessarily red. The foregoing propositions are supported by the evidence of numerous observers. That the malarial parasite will not sporulate in the dark would seem to be the opinion of a large number of those experienced in tropical diseases, the late Dr. Walter Reed, U. S. Army, stated that he could not criticise this argument; as all of his own patients suffering from malaria had had their chills in the daytime. The unrecognized factor, then, which Dr. King claims promotes the sporulation of the parasite after it has entered the blood, and in the absence of which sporulation will not take place, is the light of the sun.

A most important part of Dr. King's theory is that which deals with the action of quinine on malaria. The writer advances the following statements: That the malarial parasite will not sporulate in the dark; that the light it obtains in the blood is necessarily red; and, following the demonstrations of Harrington and Leaming, that amœba proteus streams in the presence of red light, and ceases to stream in violet light, it may be assumed that the same is true of the malarial amæba; therefore it is suggested that the curative action of quinine may be due to its fluorescence, producing violet rays of light in the blood.

The evidence adduced in favor of this part of the theory is weighty if not conclusive. First, it is pointed out that two other vegetable products possessing blue fluorescence to a remarkable degree, have long been known as effective remedies for intermittent fever, viz., esculine and fraxine. But more satisfactory proofs are given that quinine actually produces fluorescence in the body, and that coincidently the symptoms and phenomena of malarial fever disappear. Such results were obtained more than thirty years ago (1868) by the experiments of Drs. Edward Rhoads and William Pepper of Philadelphia. These experiments are too long to record here, but suffice it to say, that these physicians proved in several cases that fluorescence of the blood was greatly diminished by malaria, and that in two cases fluorescence was greatly increased, and a cure effected by the administration of sulphate of cinchona.

The author explains these cases which quinine fails to cure, by contending that in such instances the febrile paroxysm is not produced by the usual tertian or quartan parasite, but by the "malignant" crescentic form. These crescent parasites, according to Mauson, are not generally found in peripheral circulation. They are found in the spleen, liver, bone-marrow, and brain—in fact, in the darkest recesses of the body, where the fluorescent properties of quinine can exert no effect.

Into the question of the universally admitted comparative immunity of the negro race to malarial fever the limited scope of this article precludes us from entering. Dr. King's views as to the cause of this idiosyncrasy are in line with the rest of his theory.

Of course the ideas promulgated by Dr. King can be subjected to more or less destructive criticism, nevertheless, they are deserving of the closest attention. It should be borne in mind that so far back as 1883 the author brought forward the theory that the mosquito was concerned in the propagation of malarial fever and published papers upholding this opinion. He was then many years in advance of his generation, and it is not at all unlikely that he may again be right. In any case Dr. King's views are deserving of a fair trial. Experiments might be conducted, when malaria is prevalent, on an extended scale, and in accordance with the theory introduced by Dr. King. Even if it be proved

that the writer is wrong, he still will have done much good by giving a fillip to scientific research, while if it be shown that his ideas were based upon the solid foundation of fact he will have gained honor for his country and himself, and benefited mankind at large.

The Increase of Cancer.

It would appear from statistics which have been gathered within the past two or three years, that cancer is on the increase in all parts of the civilized world. The *Lancet*, April 25, in an editorial referring to the disease as it affects England, says, "From the report of the Registrar-General of England for 1900, we gather that among women who have attained their forty-fifth year of age, as well as among men ten years older, cancer exacts a yearly death-toll vastly heavier than that which is levied by that other national scourge, pulmonary tuberculosis.

The Registrar-General of Ireland has recently published a blue book of the most alarming character, so far as it draws attention to the remarkable increase of cancer in that country. Indeed, the account has given rise to a feeling almost approaching panic, throughout Great Britain, and the lay journals have been flooded with correspondence on the subject.

The *British Medical Journal* is issuing, week by week, a comparative statistical study of cancer mortality, dealing with cancer statistics in the various countries of the civilized world. In the number for May 2, the United States, Switzerland, and Italy are made the subjects for discussion. The figures for this country are taken from the twelfth census, and, of course, are both interesting and instructive. Cancer in the United States is said to have been the cause of 29,475 deaths, equivalent to a rate of 38.6 per 100,000 living. The regions showing the highest and lowest death rates from cancer and tumor were: Highest—Pacific Coast region, 51.9 per 100,000; heavily timbered region in the northwest, 46.8 per 100,000; Northeastern hills and plateaus, 44.5 per 100,000; prairie region, 43.0 per 100,000; Atlantic Coast region, 41.5 per 100,000. Lowest—Gulf Coast region, 20.2 per 100,000; South Central Appalachian region, 20.0 per 100,000; South Atlantic Coast, 18.7 per 100,000; South Interior plateaus, 18.1 per 100,000; Mississippi river belt, 11.3 per 100,000.

The death rate from cancer and tumor per 100,000 was: White, 66.7; Chinese, 49.4; Negro, 48.0; Indian, 28.6; foreign-born, 124.6. It will thus be observed that the foreign-born whites are much more subject to cancer than native-born whites, and not only this, but those who have one foreign-born parent are more liable to the disease than the native-born whites. The statistics also show that Jews contract cancer very frequently in the latter half of life, and that the cancer rate is far higher in rural than in urban districts.

The death rate from cancer of four of the most important American cities, per 100,000 living, all ages, is as follows: Chicago, 63.3; New York, 64.7; Philadelphia, 73.6; and San Francisco, 112.0.

Notwithstanding, the efforts that have been made within the past few years to trace the origin of cancer, it must, in truth, be confessed that but a very small corner of the veil which covers its secret has been lifted. Its etiology is yet to be discovered. Perhaps of all the well-known diseases of modern life, our knowledge of cancer is less than of any. The hopeful feature of the situation is that almost all civilized nations are vying with each other, and giving money and brains in the endeavor to solve the cancer problem.

Movement for the Improvement of Allen street.

It is freely allowed on all hands that prevention is better than cure. This, indeed, is an axiom. In no one disease does this statement bear so much force as in tuberculosis. The only manner in which consumption can possibly be stamped out, is by improving the conditions of life of the poorer classes. Where persons are herded together like animals, debarred from their share of light and air, it stands to reason that if in such a district tuberculosis originates, there it will spread rapidly. The soil is suitable, the environment is propitious, and if the seed be planted it will flourish exceedingly.

Allen street, in the lower East side of New York, fulfils all these conditions exactly, and in a high degree. Both light and air are lacking, and the population is dense. A crusade has been undertaken to deliver the inhabitants of this street from their distressful state. A committee has been appointed from among the settlement workers, who will use their utmost endeavors to prove to the authorities that Allen street as it is now is a scandal to the city, and a menace to the dwellers in surrounding locality. It is said that a committee of fifteen physicians is behind the movement to secure as much light and ventilation for Allen street as the other streets of the lower East side enjoy. The agents of the United Hebrew Charities, in whose district the street lies, declare that it is the worst in the city. The light is shut off from the houses by the elevated railroad structures, and the interior of the dwellings on the sunniest days are dark and dismal.

The state of affairs prevailing in Allen street may be taken as a text for a sermon on the absolute necessity of sufficient light and air for human beings to be able to live in health. The tenement district of New York is probably as crowded and as unhealthy as that of any city of the world. There is not in any part of the said district a sufficiency of light and air, and it is a source of danger, to some extent, to the entire city. It must be thoroughly understood that to prevent disease the first thing to be done is to provide the population with sanitary dwellings, and until this is accomplished diseases of all kinds will spread. The widening of Allen street would be a step in the right direction, and an earnest of further reform.

Vital Statistics.

The Census Office, in conjunction with the American Public Health Association, and other bodies, has initiated a movement to secure more complete and accurate data for vital statistics by promoting the extension of registration of births and deaths upon practical and uniform lines, and to make the registration records of greater value to individuals by insuring the proper registration of all births and deaths that occur. To further this movement, a series of circulars has been published by the Census Office, each relating to a special part of the subject. These are as follows: (1) Legislative requirements for accurate and uniform registration, including resolutions of Congress and the American Public Health Association, with a paper prepared by the Association Committee on "Demography and Statistics in Their Sanitary Relation," outlining the essential features of an adequate law for the registration of deaths, and a specimen form of a law drawn in accordance with the principles stated by the committee. (2) Practical registration methods, including a description of the "Standard Certificate of Death," with suggestions as to its use and treatment. This circular is designed for the use of regis-

tration officials, and presents a systematic method of securing complete and satisfactory returns, and of filing and preserving them so as to ensure the best results as contemplated by the law formulated in the previous circular. (3) Relation of physicians to mortality statistics, with special reference to the statement of causes of death and other details essential to completeness and accuracy. It gives the titles of "the International Classification of Causes of Death," with explanatory notes showing the meaning of titles as applied in statistical tabulation; also a long list of indefinite or unclassifiable terms very frequently used by physicians in stating causes of death, with notes showing why they are unsatisfactory, and indicating the further information necessary to permit their proper classification. (4) Manual of the "International Classification of Causes of Death" as adopted by the Census office and approved by the American Public Health Association. This is designed for the use of officials who compile statistics.

The Census Office has acted wisely in sending out these circulars. The one on medical education in vital statistics is especially to the point, as medical colleges are best able to carry on this much-needed instruction. The manner in which some physicians make out certificates is decidedly unsatisfactory. By studying, however, the circular on the "Relation of Physicians to Mortality Statistics," and acting upon the advice tendered therein, they can render the work of the Census Office valuable for scientific purposes. So inaccurate are many of the death certificates sent in at present, that they are comparatively useless for the compilation of mortality statistics.

News of the Week.

Parasitic Diseases and Predisposition.—Dr. A. L. Benedict of Buffalo, N. Y., writes: "Will you kindly allow me to present the following proposition through your columns. Without expressing a personal opinion, I would like to collate those of clinicians, sanitarians, and pathologists and would suggest that, to insure their receipt, they be sent to me in the form of private correspondence or references to literature.

"Of all diseases due to parasites, of whatever kind, tuberculosis alone clearly illustrates predisposition by general states of the organism of the host, independently of opportunities for infection and of plainly local lesions or cellular states (as in regard to the malignant neoplasms, if these be considered parasitic) which favor colonization of the parasite. Even in the case of tuberculosis, these latter factors outweigh purely general conditions of diminution of resistance."

Arguments in Justification of the Galveston Quarantine Regulations against Cuban Ports.—Dr. Edmond Souchon, M.D., President of the Louisana State Board of Health sends the following:

Cuba has been for 130 years the hot bed of yellow fever.

It is only two years ago that yellow fever was not reported from there.

That does not mean that there are no mild cases unknown, unrecognized, or unreported.

Epidemic diseases are often dormant and then break out again.

We are not so sure as yet that fever will not spring up in Cuba—in Havana, especially.

No attention is paid in Cuba to baggage, bedding, and fomites in general from vessels from infected ports or from the Yellow Fever hospitals.

The Louisana State Board is not as yet prepared to accept this procedure as safe.

Infected baggage, bedding, and other fomites may reach Louisiana.

It is the first year really that the Cubans are managing the health matters of the Island, and we will wait to see with what final result.

We desire to be liberal toward our neighbor, but not at the risk of suffering ourselves.

We have done away with detention this year and have limited our regulations to baggage and mosquitos.

We will require that Cuba goes through one year more of probation before removing all restrictions and precautions.

We are told that these precautions are unnecessary.

We are the sufferers when yellow fever and quarantines break out and not our would-be advisers.

We claim to know better what is best to protect ourselves than the partisans of Cuban commerce or officious advisers, or even official advisers.

Florida, we are told, has removed all restrictions against Cuba. Florida depends so much upon Cuba that it must take risks that we do not approve of and will not take.

We are urged to follow the advice of Dr. Wyman and the U. S. Public Health Service and consider Cuba free from any possible risk. But Dr. Wyman and the U. S. Public Health Service will not be the sufferers if yellow fever appears in Cuba and reaches Louisiana. We will be the sufferers.

We positively decline to run the risk of being caught with all the bars down. We refuse emphatically to run the risk of another epidemic to prove that yellow fever is still lurking in Cuba.

To guard against all risks, all baggage is sealed before being admitted on board of the vessel, but it is not disinfected at the port of departure, pyrethrum powder is burned on board against the mosquitos, and the temperature of every passenger is taken before the vessel leaves.

Upon arriving at the Mississippi River Quarantine Station the vessel is regularly disinfected. There is no detention of passengers unless there is sickness.

Owners of baggage from Florida Ports and from Jacksonville (Fla.) coming to Louisiana shall have to satisfy the Inspector of the Louisiana State Board of Health that they do not come from Cuba, or their baggage shall be held at Louisiana Line or Stations for inspection and disinfection.

The quarantine regulations of Louisiana against Cuba are also practised by Texas and the Quarantine Board of Mobile Bay.

Dinner to Dr. Charles A. Powers of Denver, Col.—Dr. William T. Bull gave a complimentary dinner, May 17, at his residence, to Dr. Charles A. Powers, formerly of this city, the recently elected chairman of the Surgical Section of the American Medical Association.

Street Sign Bills Held Up.—The officials of the Department of Finance and President Cantor cannot agree as to the expenditures for street signs made under the authority of the Board of Estimate. President Cantor was allowed $40,000 to put up street signs, and of that sum he has spent more than $26,000. The work has all been done by Joseph N. Early. Up to the present time Mr. Early has supplied the city with street signs valued at $19,900, and additional orders have been given him. The officials of the Finance Department now assert that the last orders were given without public letting of any contract, and have refused to audit the bills sent over by President Cantor, and the matter has been referred for arbitration to Corporation Counsel Rives. It is devoutly to be hoped that this quarrel will not delay the putting up of the much-needed street signs throughout the city. New York has already been too long without these necessary aids to direction.

Pavilion for the Deaf.—On May 12 the Schermerhorn Aural Pavilion, the gift of the late William Schermerhorn to the New York Eye and Ear Infirmary, on Second Avenue, was dedicated. This addition, which cost $75,000, contains two operating rooms, special rooms for patients with brain complications and a separate ward for children. The most interesting part of the opening ceremonies was the delivery by Joseph Jefferson of an address composed by Helen Keller, the deaf and blind girl.

A Crusade against Scents.—Atlanta, Ga., it is said is soon to have an ordinance which will bar

persons carrying odors from riding on street cars. By "odors" the Council means those scents which emanate from individuals who work in factories, and especially in guano factories, of which there are many in Atlanta. So loosely framed, however, is the ordinance, that it will be left to the discretion of the conductor and passengers as to what constitutes an unpleasant odor, and the former will have the power to eject any person from whom proceeds a smell offensive to any other passenger.

Complimentary Dinner to Dr. Hans Kehr of Haverstadt, Germany.—Dr. Hans Kehr, so well known by his original and extensive work in gall stone surgery, was the recipient of a well-deserved courtesy on the occasion of his recent visit to New York, after his attendance at the Washington Congress. Dr. Willy Meyer tendered him a banquet at Delmonico's on Tuesday evening last, at which twenty-five of the representative surgeons of this city were present. On Wednesday Dr. Kehr gave an operative clinic at the German Hospital, by invitation of Prof. Willy Meyer; also one on Thursday at Bellevue, by invitation of Prof. F. B. Farquar Curtis, and one at the Post-Graduate Hospital, occupying the clinic hour of Dr. Willy Meyer. In each instance he demonstrated his methods of gallstone surgery.

Statue to Major Reed.—A movement is on foot to induce Congress to authorize the erection of a statue in honor of the late Major Walter Reed, who effected so much in proving the theory that yellow fever was propagated by mosquitos. The success of his researches in Havana made his name famous in all parts of the world. and no medical man of the present generation has more fully deserved well of his country than Major Reed. It is eminently fitting that due honor should be paid to his memory.

Automobile Bill Signed by the Governor.—Governor Odell, despite protests from those connected with the automobile trade and social organizations in all parts of New York State, has signed the Doughty-Bailey bill. The salient points of the new law are: Speed restricted to four miles an hour when crossing a dam or causeway of less than twenty feet in width. Speed restricted to eight miles an hour within a radius of half a mile from a post-office or a greater radius if local authorities so elect, when passing in either direction, a person driving a horse or domestic animal, or passing a pedestrian in the roadway; when crossing an intersecting main highway; in the closely built-up portions of cities. Speed restricted to ten miles an hour, when passing a public school during school hours, or a church during the hours of service. Speed restricted to ten miles an hour in the suburbs of cities where the houses are more than one hundred feet apart. Speed restricted to twenty miles an hour in the open country where post-offices, school-houses, churches, causeways, cross-roads, drivers, or pedestrians do not conflict. A motor must be stopped on request of a rider or driver. The penalties are: First offense, not exceeding $50; second offense not less than $50, nor exceeding $100, or imprisonment not exceeding thirty days or both; for third offense, imprisonment not exceeding thirty days and fine of not less than $100 nor exceeding $250.

Bills Relating to Medicine and Public Health Signed by the Governor.—Governor Odell has, after all, signed Senator McEwan's Barber Bill. It establishes a State board of barber examiners, and provides for the sanitary inspection of barber shops.

The following bills were vetoed: Assemblyman Bostwick's Substitution of Drugs Bill, Senator Martin's Inebriate's Home Bill.

Epidemic of Pneumonia in Chicago.—Surgeon Banks of the Marine Hospital Service, according to the *New York Tribune*, has made a report to the central office of that service in Washington relative to the prevalence of pneumonia in Chicago. He says that the disease has almost reached epidemic proportions. Of the 5,341 deaths from all causes in the city in two months, Dr. Banks says that 1,186, or 22 per cent., were caused by pneumonia.

Anniversary of German Poliklinik.—The twentieth anniversary of the founding of the German Poliklinik was celebrated by its members on the evening of May 16. In addition to celebrating the anniversary, the members of the board of trustees honored the five surviving founders, Dr. Samuel Kohn, C. A. von Ramdohr, Ludwig Weiss, H. J. Boldt, and C. E. Denhard. Dr. Edward Benneche, President of the Poliklinik, made the principal speech, addresses were also made by Drs. Carl Beck, S Kohn, C. A. von Ramdohr, and S. Britenfeld.

Graduation of Nurses.—Sixty-four nurses attached to the City Maternity, Gouveneur, Harlem, and Fordham hospitals were graduated at the twenty-eighth annual commencement of the New York City Training School for Nurses, which took place on May 16, on Blackwell's Island. Of this number seventeen were from the graduate course.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

INFECTIVE ENDOCARDITIS—CONGENITAL HYPERTROPHY OF THE EXTREMITIES—BRADYCARDIA—CRETIN WITH CYANOSIS OF THE LIMBS—MEDICAL MISSION—HOSPITAL SATURDAY FUND—ZOOLOGICAL SOCIETY—NOTES.

London, May 1, 1903.

The Lumleian Lectures this year were delivered by D. T. R. Glynn of Liverpool, who took for his subject infective endocarditis, a disease to which he has long devoted much attention. He was able to illustrate his lectures by numerous colored drawings which he made during his tenure of office at the Liverpool Royal Infirmary, of which he is now consulting physician. These drawings represent the morbid appearances of the heart, characteristic of the various forms of disease to which it is subject, and which, therefore, illustrate infective endocarditis by contrast with other lesions. The morbid changes produced by endocarditis were carefully described long before their clinical associations were suspected, and Dr. Glynn quoted observations recorded by Morgagni (1769), Senac (1749), Matthew Bailey (1807), and a number of authors since. To Bouilland must be ascribed the honor of recognizing first the relationship between rheumatism and simple endocarditis, and also the association of ulceration of the cardiac valves with symptoms of typhoid fever. These points he distinctly laid down in his *Traite Clinique* (1824). Nearly thirty years elapsed before Kirkes (1853) enunciated the embolic theory, and demonstrated the lesions and clinical features of ulcerative endocarditis, though he confined his study to the consequences rather than the nature of the disease. Soon after came the dawn of bacteriology. In 1855 Rokitanski indicated the presence of bacteria in the vegetations, and was confirmed by Virchow and others. With the rapid progress of bacteriological technique, it soon became evident the infective endocarditis is not a specific disease due to one species of microorganism, but is produced by different varieties, notably the streptococcus, staphylococcus, and pneumococcus.

For some time the disease was regarded as a local one, which generalized itself by introducing into the blood products formed at the valves. But it became evident that organisms could only reach the valves through the circulation. Then it was clear that a local lesion, as in pneumonia, typhoid fever, and other diseases, might favor the entrance of pathogenic organisms and their multiplication in the system. The simple and infective forms of endocarditis are difficult to distinguish, and both having been shown to be due to microbes, the difference between them seems to be only one of degree. The terms "infective" and "non-infective" would be better discarded, as Dr. Glynn thought them hardly justifiable,

and suggested that malignant would be more appropriate, only it has been otherwise applied. The manner in which the organisms may enter the system was discussed by Dr. Glynn, but he had to confess that in the majority of his cases he had not been able to trace it. He classified his cases according to the severity and duration of the symptoms, as acute, subacute, and chronic. The great majority were of the chronic type, the symptoms persisting for several months. Perhaps this proportion was due to the diagnostic sagacity which Dr. Glynn brought to bear on his patients.

With regard to the treatment of infective endocarditis, not much can be added to what Sir Douglas Powell had to say in his Lumleian Lectures for 1898. The success of anti-streptococcic serum has not equalled the expectations formed. Perhaps a polyvalent serum may prove more efficacious. Sir D. Powell's table of cases gave successes in 25 per cent. Dr. Ogle drew up a table showing 31.5 per cent. Dr. Glynn has used the serum three times without success, but he deprecates a despondent attitude for recovery in desperate cases is possible, and the physician must patiently follow rational indications.

Two children with congenital hypertrophy in the lower extremity were shown at the last meeting of the Clinical Society. One was a girl of three and a half months. A difference in the size of the legs had been noticed when two weeks old and had increased ever since. The right foot is now one-quarter inch longer than the left. The enlargement of the leg is symmetrical, greater at the proximal than at the distal extremity, mostly composed of soft tissues, but a skiagram shows that the bones are also enlarged. There is no other abnormality.

The other case is a girl of four and a half months. Enlargement of left leg was noticed at birth and of the thigh when she was two months old. The leg is about one-quarter longer than the right. There is asymmetry of the cranium, causing a projection on the left side and the face is fuller on that side. No other abnormality but a capillary nævus on the back.

At the same meeting there was a man of forty-six years who had a sunstroke in 1901. Since then his pulse rate has ranged between 20 and 36; it is not known what it was before. The left ventricle is large, the apex beating under the fifth rib just outside the nipple line: no other abnormalities about the heart. Since the sunstroke he suffers from syncopal attacks, at first four or five a day, but lately seldom: about six last year. He has a momentary dizziness, then complete unconsciousness for four to eight minutes. Neither convulsions nor paralysis. These attacks seem to resemble some described by Osler as "Adams' disease."

A girl of three years and nine months was shown who has a typical cretinoid appearance with cyanosis of the extremities which was to have been noticed two years ago and which varies a good deal from time to time. She has learned to walk. She can only say a few words. The heart sounds are feeble, but there is no murmur.

For months past the Zoological Society has been agitated by the determination of prominent Fellows to enforce some much-needed reforms. On Wednesday the climax was reached when the meeting was attended by 870 Fellows and a new secretary elected by a majority of 194 votes. The ballot was taken without any excitement, no discussion of the claims of candidates being allowed at the meeting. Dr. Chalmers Mitchell, a well-known naturalist, was elected, and will no doubt set about the many reforms which are needed.

Some suggestions were made to the Council as to the comfort of the animals kept in the gardens. I would add to them that they should be better fed. Why should the lions in the Dublin Zoo breed and in London not? I believe in London their food is insufficient. They seem always hungry.

An income of £22,964 was reported to the annual meeting of the Hospital Saturday Fund on the 26th ult. Sir S. Crossley, M.P., Chairman of the Fund, said it was feared in some quarters that the abolition of the street collections would lead to considerable loss, but that fear had not been realized and a substantial increase had been received, mainly from the workshop collections. The Lord Mayor, who presided, expressed his pleasure at the satisfactory nature of the report, especially with regard to the support of the working classes.

Sir E. H. Currie expressed his fear that hospitals would have to be maintained by the rates unless managers kept down the expenses, which are now much higher than ten years ago. He urged that the three great hospital funds—the Kings', the Sunday and the Saturday—should unitedly take steps to make managers keep down expenses.

The report was adopted, the Lady Mayoress distributed certificates in first aid and nursing, and Dr. T. D. Lister read a paper on "Infant Feeding and Milk Supply," in which he dwelt on the great infant mortality of our large towns due to improper feeding. The milk supply, he said, required the most careful supervision to secure immunity from contamination. The municipal milk depots in Battersea and St. Helens, he reckoned, had saved 60 to 70 lives per 1,000 compared with the average infant death rate of those boroughs.

A new accident and surgical ward erected by the Billingsgate Medical Mission was opened on Tuesday by the Lord Mayor. It has cost £7,500, of which £2,000 remains to be provided.

The Lord Chief Justice of England presided at the annual festival of King's College Hospital on Tuesday, and speaking of the services rendered by the hospital to the community made a strong appeal for increased support. Subscriptions amounting to £2,143 were announced.

The Jews Hospital and Asylum is fortunate this year. The dinner presided over by the Lord Mayor was given at the Mansion House on Wednesday, and the subscription list amounted to £15,300.

Mr. Foulerton has resigned the Directorate of the Cancer Research Laboratories of the Middlesex Hospital to make way for a director who can devote all his time to the work.

Mr. Foulerton will continue to direct the clinical and bacteriological work.

The death is announced of the Hon. M. S. Grace, C. M. G., a member for many years of the Legislative Council of New Zealand, in which colony he settled in 1860. He was for many years in the army and attained the rank of Surgeon-General in the colonial forces. He died on the 19th ult., at Wellington, N. Z.

THE MISMANAGEMENT OF THE FOURTEENTH INTERNATIONAL MEDICAL CONGRESS.

To the Editor of the Medical Record:

Sir: It is impossible to convey to one not present the inconceivable lack of system prevailing at the Madrid Congress. The building in which the section meetings were held, and in which was the registration office was the National Library and Museum in the Paseo de Recoletos. Although it had been known for two or three years that the building would be used for this purpose, shortly before the congress met the government decided to make some alterations to the front of the structure. A huge scaffolding was erected, defacing the building and closing the handsome main entrance, and the members of the congress were forced to use the back door, and then wander through a maze of rooms and cross a bridge before getting to the office of registration. This office, where the programs and badges were given out, was a narrow passage-way ending in a cul-de-sac, wide enough to admit three persons walking abreast, and into and out of which surged for hours a mass of perspiring humanity, shouting, stamping, gesticulating, and swearing in all the tongues of the earth. Although the town was full of congressists for a week before the opening, the programs and badges were not ready for distribution until four o'clock in the afternoon preceding the opening day. The section meetings were held in the second floor of the same building in a series of rooms opening one into the other, and through which was a continual tramping of members going to other sections, the noise of which effectually drowned the voices of those reading papers. The commotion was much greater than need be, because each man was left to find his own section as best he could, no plan of the distribution of sections having been prepared until the congress was half finished. The general sessions were held at irregular intervals in the amphitheater of the medical school, two miles distant from the place of section meetings, and notice was given of but one of these general sessions to the members of the congress. The general program, be it remarked in parenthesis (a pamphlet of sixty-four pages), contained not one word regarding the order of exercises, save of the general sessions, and this was incorrect in every particular. Diligent inquiry made each morning of officers of the congress regarding the holding of the general session sometimes was rewarded by the statement that, owing to the great confusion, the secretary could not say when the next session would be held, sometimes by the assurance that a meeting would be held that day at three o'clock. The seeker after knowledge would then go to the medical school at the appointed hour and wait and wait and wait until his patience was exhausted, and then go home. After he had gone two or three addresses would, perhaps, be read before an audience of twenty or thirty medical students. The attendance at these general meetings, it is needless to say, was so exceedingly scant as to be actually insulting to the orators. At the opening session the same mismanagement was in evidence. Hundreds of the members of the congress were unable to get into the opera-house, the seats and boxes being filled at an early hour by

non-medical residents of Madrid. The delegates of several foreign governments, of the United States among others, were refused admission to the stage and, consequently, were unable to speak when the names of their respective countries were called. Some of the Americans present thought this exclusion was intentional, but it was nothing of the kind—merely one more example of the incredible blundering which characterized every move of the congress managers. No record was kept of the addresses of the members, and consequently it was impossible to find anyone wanted, many instances being known of friends from different countries having made a rendezvous at the congress, but failing to meet. An elaborate list of entertainments to be given in honor of the congressists was published weeks before the meeting, but no arrangements were made for those entertainments until shortly before the opening, and then it was too late. The result was, that the audience of the king, the garden party in the palace grounds, and that in the Buen Retiro Garden were the only general entertainments carried out according to program. The conduct of the excursions to the Escorial and to Toledo which had been planned for the entertainment of the congressists, was turned over to the "Voyages Pratiques," a tourist concern, which charged for each of the excursions from eight to ten pesetas more per individual than one would have to pay traveling alone. Some of the receptions announced to be given by the city council and other public bodies came off, but the number of invitations was limited and few of the foreign members or delegates were present, the officers of the congress having the distribution of the tickets. The "Bureau des Logements," which had been charged with the securing of lodgings for the congressists, must have had enormous expenses to meet, for it charged the men who had confidingly put themselves in its care from 50 to 100 per cent. more than it paid the persons from whom the lodgings were hired. It did not permit the member to pay his host directly, but payment had to be made by coupons bought of the committee on lodgings, and in this way only a few of the wiser ones and those who spoke Spanish learned of the difference between what they paid and what the owner of the house received. It was announced that the railways of France and Spain would grant a reduction of 50 per cent. on the price of tickets to those attending the congress. On the strength of this announcement many foreigners sent their subscriptions to the congress months ahead, receiving a card of membership on which was printed the statement that on presentation of the same at the railway ticket office the promised reduction would be allowed. But nothing of the kind. Special cards were necessary to secure the reduction, and those were generally sent to members too late to reach them before setting out for the congress, and in many cases they were not sent at all, even in response to urgent letters and telegrams. There was, of course, no design here of making money out of the congressists (the Bureau de Logements was the only department concerning which such a suspicion was tenable), but it was simply one more example of the phenomenal lack of system and infantile mismanagement which characterized the administration of the entire congress from the moment of its conception to the closing meeting on the last day of April.

This is a strong arraignment of the officers of the Fourteenth Industrial Medical Congress, and it may seem ungracious on the part of a member of the congress to write it. But it is true and without exaggeration, and it is but right to state the facts, most of which were commented upon by the Madrid papers published during congress week. It is not a pleasure jaunt to attend an international medical congress, for with the best of management there must be some discomfort from crowded trains and overflowing hotels, and it is the bounden duty of the men who have invited the physicians of the world to gather together for scientific discussion in their country or their city to see that the inevitable discomfort is reduced to a minimum. If they fail to do so they have been recreant to their trust and have abused the confidence of their fellows in other lands who had honored them by consenting to accept their proffered hospitality. This is what the organizers of the fourteenth international congress failed to do—and it is proper to note their dereliction.

A VICTIM.

GIBRALTAR, May 3, 1903.

Suspension of Dr. Weston.—As a result of his failure to appear as a witness at the trial of Gertrude Wade for manslaughter on May 11, after a subpœna had been sent to his home, Coroner's Physician Albert T. Weston has been suspended without pay until he has satisfactorily explained his absence.

Progress of Medical Science.

New York Medical Journal, May 16, 1903.

The Relation of Cholelithiasis to Acute Pancreatitis.—J., Wiener, Jr., reports a personal case and gives brief notes of thirty-two others. He considers that, from a study of these cases it is evident that there must be a connection between the two conditions. In not a few instances positive proof was found at the autopsy that the duct of Wirsung had been occluded by a gallstone. In one case a biliary calculus had actually found its way into the pancreatic duct. In another case there was a history of several attacks of biliary colic followed by jaundice. Then came the fatal attack of acute pancreatitis. At the autopsy the common duct was found enormously dilated, and in the duodenum was found the large calculus which had undoubtedly caused the duct occlusion. Is it not fair, asks the author, to assume that in some of the other cases, in which the offending calculus was not found, it had passed further down into the bowel?

The anatomical conditions in some cases certainly predispose to an obstruction of the pancreatic duct at the papilla. Fortunately, the relations of the two ducts are often not favorable to the occlusion of the duct of Wirsung, or else there would be many more deaths to report from acute pancreatitis in gallstone cases. However, the cases in which pancreatic obstruction does occur in this manner are another potent argument in favor of early operation, not only for cholelithiasis, but also for acute pancreatitis. The thirty-two previously reported cases all ended fatally, because, in many of them, operation was too long deferred. The author was fortunate in saving his own patient, not because he made an early diagnosis, but because he advised an early exploratory incision. And this is, he believes, the crux of the whole problem. Many of the foregoing cases could have been saved had an early operation been resorted to. That the diagnosis in the early stages of acute pancreatitis is, in most cases, extremely difficult, has already been mentioned. But it is just in these doubtful cases that most brilliant results may be achieved by early resort to the exploratory incision.

Philadelphia Medical Journal, May 16, 1903.

Tetanus: A Study of Fifty-seven Cases from the Records of the Pennsylvania Hospital.—George William Norris calls attention to the following facts: Tetanus toxin is found mainly in the nervous tissues; once united with these, antitoxin is powerless in its action on already affected cells. Antitoxin is harmless, but deteriorates rapidly; therefore, it should be procured fresh, and administered in continuous and large doses with the hope of immunizing the intact nerve cells. All cases of wounds in which there is a possibility of tetanic infection should receive prophylactic injections of antitoxin. Local treatment is of great importance, hence the infected area should be excised; when this is impossible, extensive disinfection, preferably with carbolic acid, should be carried out; furthermore, as Behring has shown, antitoxin is of benefit locally as well as systematically. Every effort should be made to maintain the nutrition of the patient, for Castronuovo has demonstrated that antitoxin is of no value in tetanic animals which have been starved.

Gastric Carcinoma Associated with Hyperchlorhydria and with Attacks of Stupor.—Norman B. Gwyn reports this case. He says that the mere persistence of free HCl in gastric carcinoma is not unusual, but an acidity as high as in this case—the total acidity being 70, and a free hydrochloric amount of 55 being determined, four months after onset—is distinctly out of the ordinary. At the first observation an occasional thickening could be felt in the epigastrium and right hypochondrium. The mass continued to grow and cachexia developed. Seven months from onset there was a total acidity of 40 and free HCl of 25. The patient was first seen in March. During the fall and winter small nodules developed just below the ziphoid cartilage, seemingly subcutaneous. On four occasions within the last six months the patient showed an unusual condition of intense stupor on four occasions. The origin of this stupor is obscure. It was perhaps due to a toxæmia of some sort. The patient refused operation.

Medical News, May 16, 1903.

Notes on Blood-pressure in Man.—S. S. Goldwater declares that thus far active mental states have been spoken of chiefly with regard to their ability to effect an exaltation of arterial tension. But while psychical functionation is capable of influencing arterial tension in the manner described, an undue prolongation of mental strain may have the contrary effect. In tracing normal blood-pressures during a period of twenty-four hours, there are seen tremendous changes which are associated

with modifications of the conscious state. In the curve, based on the writer's own observations, a rise is shown as a result of a lively argument. Unquestionably a large part of the almost constant rise of pressure from the hour of rising in the morning until the hour of retiring at night, is due to a succession of similar influences.

Journal of the American Medical Association, May 16, 1903.

Theories of the Transmission of Hereditary Syphilis.—A. Schalek believes that so far as the father is concerned, that infectious material may be communicated to the ovum by external agencies, including the semen, and result in a diseased product. From the ideas he advances the following conclusions may be drawn: (1) The father's sperm cell may contain the syphilitic virus and convey it to the child without participation of the mother. (2) The maternal generative cell may contain the virus and result directly in a diseased fœtus. (3) The placental circulation permits the passage of the infectious matter either way from mother to child, and vice versa. (4) Several or all of these factors may combine, and the more of them that are present the less probable the escape of the child. (5) The probabilities of the transmission of syphilis through the mother are greater because of more ways of possible influence on the fœtus. He considers the probability of the appearance of hereditary syphilis to be reversely proportionate (1) to the time of infection of the parents, and (2) to the length and thoroughness of the specific treatment. To answer the question as to whether or not syphilis can be transmitted to the second generation, he believes that we must have positive evidence (1) of acquired syphilis of either, or of both, of the grandparents; (2) of hereditary syphilis in either of the parents with the absolute proof that no new syphilitic infection of the parents took place, and (3) of hereditary syphilis in the grandchildren. The difficulties attached to the task of acquiring a trustworthy history of a disease running through three generations, make the reliability of the reported cases very uncertain, and do not, therefore, permit any correct deductions.

A Case of Rodent Ulcer.—J. C. O'Day considers his case worthy of report because of the extensive destruction of the face and the compatibility of a fair degree of health extending over a period of ten years. His patient was a male, aged fifty-six years, married, father of five children, living and well. The family history was negative. The personal history was negative, except that prior to the onset of ulcer the patient drank considerably. Sixteen years ago a small pimple appeared over the right eye becoming pustular and painful. The patient consulted a physician, who opened it with a needle, allowing the pus to escape. The margin now began to break down until the eyelid was threatened. Every effort to arrest the destructive character of the disease not only proved fruitless but seemed to aggravate it. In spite of various methods of treatment the disease progressed steadily, attacking skin, muscle, bone, eyes, nerves, and all structures of the face. This continued six years, when the destructive tendency ceased. For the past ten years it has remained in about the same condition. Examination shows the complete loss of the superior maxillæ, including all the soft structures up to the horizontal portion of the frontal bone. The tongue and remnant of the upper lip remain. In eating, he has his food minced and made into gruel with milk. This, with the aid of a spoon, he throws back on the base of his tongue, and it is readily swallowed. Words of the full vowel sound he utters distinctly, but with a peculiar horn-like pitch. He writes readily with slate and pencil, and in this way makes his wants known.

American Medicine, May 16, 1903.

Congenital Dislocation of the Hip: Report of a Bloodless Reposition, Followed by Death, with an Analysis of Twenty-three Cases in Process of Treatment.—H. Augustus Wilson, J. Torrance Rugh, and W. M. L. Coplin, in reporting a number of cases, state that in not one case has there been any evidence of paralysis or other nerve disturbance. Pain on attempting to use the leg operated upon has generally persisted for two to four days, and after that was only present when the hamstring tendons were stretched in those cases in which some flexion of the knee persisted. This, however, soon subsided, and freedom from pain or annoyances of any kind has been the condition in all cases excepting only the inconvenience of the plaster cast and the position in which it held the leg. It was a matter of great interest to see how quickly the children learned to adapt themselves to the posture of the affected leg, and to use it in walking where only one hip had been replaced.

Heart Showing Chronic Tuberculosis of the Pericardium, with Involvement of the Myocardium.—A. G. Ellis exhibited a specimen obtained at autopsy from the body of a male negro, aged twenty-four years, who died in October, 1902. The mediastinal tissues were studded with variously-sized grayish or yellowish nodules, some of which had caseous centers. The heart and the mediastinal tissues formed practically one large adherent nodular mass. Both pleuræ were universally adherent. The pericardium was universally adherent, the external surface being studded with yellowish nodules, varying from 0.2 to 2 cm. in diameter. In a number of places these nodules extended into the heart muscle, in some instances to a depth of more than a centimeter. The involvement of the heart was the greatest in the left ventricle, but was quite extensive in the right. The liver, spleen, pancreas, and kidneys contained miliary tubercles.

The Surgical Treatment of Pruritus Vulvæ with the Report of a Case Cured by Resection of the Genitocrural, Ilioinguinal, Inferior Pudendal, and Superficial Perineal Nerves.—Barton Cook Hirst states that the treatment of idiopathic pruritus vulvæ is among the unsolved problems of gynecology. The surgical treatment seems to promise better than the application of other remedies which are ordinarily suggested. The writer describes the operation of resecting the nerves supplying the vulva. It is too early as yet to decide what the ultimate outcome of this operation will be in a number of cases, but it seems reasonable to expect a greater certainty in results than has hitherto been obtainable by any treatment for pruritus. The writer has recently cured an intractable case with the characteristic history of having consulted several specialists and general practitioners without relief.

British Medical Journal, May 2, 1903.

Remarks on the Operative Treatment of Chronic Facial Palsy of Peripheral Origin.—Charles A. Ballance, Hamilton A. Ballance, and Purves Stewart conclude that: (1) Peripheral facial palsy is remediable by facio-accessory anastomosis, but the extent of recovery appears to be limited to associated movements in conjunction with the shoulder. In most cases the previous deformity disappears when the face is at rest. (2) For reasons above stated, he would in future recommend facio-hypoglossal anastomosis rather than facio-accessory. (3) The cases suitable for operation are those in which the paralysis had lasted so long that no recovery is to be expected, say, facial palsy lasting six months without any sign of recovery. In our opinion the sooner the operation is done after this date the better. (4) A suppurative causal condition producing an infective neuritis renders the prognosis after operative treatment less favorable than in cases due to trauma.

Graves's Disease in Association with Rheumatoid Arthritis.—R. Llewellyn Jones says that the result of his experience seems not so much to suggest an affinity between the two diseases, but rather to indicate that they often co-exist. This statement seems justified by the fact that he has seen cases, which, in addition to rheumatoid arthritis, showed the four cardinal symptoms constituting the so-called complete type of Graves's disease. It is interesting and possibly significant that many of the so-called secondary features of Graves's disease occur in the subjects of rheumatoid arthritis, and, moreover, in cases in which none of the cardinal symptoms of Graves's syndrome are present. In some of the cases reported the Graves's syndrome preceded the joint affection. In the majority the two diseases, as far as ascertainable, arose together. In a few, Graves's syndrome was of more recent date than the rheumatoid arthritis. Radical treatment, if possible, of such conditions when present, could not fail to be of benefit to the general health of the patient, and in early cases the joint condition.

British Medical Journal, May 9, 1903.

A Lecture on Therapeutic Inoculations of Bacterial Vaccines and Their Practical Exploitation in the Treatment of Disease.—A. E. Wright concludes: (1) We have seen that we have in connection with every immunization process a sequence of negative and positive phase followed in the case in which the inoculation is successful by the maintenance of a higher base line of immunity. (2) We have seen that the inoculation of an excessive dose may involve a risk, in particular, the risk of an undue prolongation of the negative phase. (3) We have seen that the inoculation of a series of doses of a vaccine will, in the case in which the inoculations are uncontrolled by intermediate blood examinations, involve the possibility of the production of a cumulative negative phase. (4) We have seen that the cumulative positive phase which is a desideratum either in itself or as leading to the maintenance of a high base line of resistance, is achieved only when the successive doses are properly adjusted and when the inoculations are appropriately interspersed. Finally, when all possible has been done in the way of guarding a patient against the risks attaching to the negative phase, the success of a therapeutic inoculation

cannot be guaranteed. The success must in each case depend upon the power of response which is possessed by the individual. In the case of a particular patient that power of response may fail us. It also may in connection with particular bacterial infections. But it may be predicted that success will in some cases be achieved.

On Exaltation of Bacterial Virulence by Passage in Vitro.—E. A. Shaw says that given volume of fresh serum having the power of killing off all the bacteria in a given volume of a bacterial emulsion of known strength, and failing to kill them all off in the same volume of an emulsion of greater strength, presumably the survivors would be the ones possessed of the greatest powers of resistance, the slain being those possessed of the least; and by allowing the survivors "the fittest" to propagate their species in serum, and so continuing to eliminate the weakly and unfit, one ought ultimately to arrive at a generation of increasedly healthy, vigorous, and resistant bacteria of the particular species subjected to this selective process, that is, a generation in increased virulence.

Acute Rheumatism and Sepsis.— Joseph A. Arkwright states that an ordinary infectious follicular tonsillitis, which is said to be usually due to the streptococcus pyogenes, is apparently the commonest exciting cause of an attack of acute rheumatism, though no doubt a predisposition strong or weak must also exist, and symptoms very closely resembling or identical with rheumatic fever occur, with scarlet fever and the scarlatinal sore throat. That other local septic processes may precede and apparently cause attacks of acute rheumatism is not so generally recognized. In certain of the cases here presented an acute local septic process appears to have set up acute rheumatic symptoms. In another case the arthritis caused was more like what is usually considered a septic arthritis, but the patient was a rheumatic subject. In one case there was no history of acute rheumatism in any blood relation, but the joint pains yielded to salicylates, and the patient had an appearance suggesting the rheumatic predisposition.

The Lancet, May 2, 1903.

The Dietetic Factor in Health-resort Treatment.—A. P. Luff discusses this question and says, concerning the dietetics of gout, that it is desirable to have as little complexity as possible. In a few intractable cases of chronic gout it may even become necessary to reduce the dietary for a time to the simplest possible condition—namely, to two articles—lean meat and water. There are a few cases of chronic gout which undoubtedly improve and even recover on an exclusive diet of red meat and hot water. These are generally cases of chronic gouty arthritis which have failed to yield to the ordinary methods of treatment and which are accompanied by obstinate derangement of the gastrointestinal tract, as evidenced by dyspepsia, flatulence, acid eructations, pyrosis, and offensive stools. He has successfully treated a few such carefully selected cases of chronic gout by the employment of this, the so-called "Salisbury" treatment. It is essential before placing a patient on such diet that the urine should be carefully examined, as any advanced condition of kidney disease contraindicates the employment of such a dietary. If the evidence of kidney derangement is only slight the adoption of the dietary is not contraindicated, but the urine must be carefully examined every two or three days, as any considerable increase in the albuminuria would at once be an indication for the discontinuance of this special diet. Gouty patients suffering from organic heart disease with any failure of compensation should never be placed on this dietary.

A Case of Tuberculous Peritonitis; Spontaneous Recovery.—The patient of H. F. Bellamy was a child of eight years presenting the usual evidences of tuberculous peritonitis. A guarded prognosis was given and the usual measures ordered, stress being laid on rest in the recumbent position, fresh air, sunshine, and careful feeding. Two days later a yellow discoloration was noted in the region of the umbilicus and was considered as a mere pigmentation, such as occurs in cases of abdominal and other tuberculous conditions. This discoloration gradually spread over the body and the condition resembled general icterus. The cause of the latter was judged to be an enlarged mesenteric gland pressing on the bile-ducts. Nourishment of the patient was a most difficult task. The article of diet best borne was milk and milk puddings thickened with Roborat, a German preparation of vegetable albumin. This was well retained, and proved a sheet anchor as to nutrition. The condition of the child gradually changed for the better. It was kept out of doors all the time, meat essences were gradually added to the diet and finally the child became well enough to be taken on a sea voyage. After an absence of eight months, it returned in good health and was able to follow the usual pursuits of children of its age.

The Relation of Meconium to the Fetal Appendix.—A. Low states that the disposition of meconium with reference to the different portions of the fetal canal is as follows: (1) *Small intestine.*—Meconium begins to distend the lower half about the middle of the fourth month and continues to do so to a variable extent till the end of fetal life. (2) *Large intestine.*—Meconium begins to distend the rectum about the beginning of the fifth month, thereafter tending to accumulate in the cæcum and then gradually distending the whole of the large intestine, so that after the seventh month dark-green meconium distends the large intestine in its whole length. (3) *Appendix vermiformis.*—Meconium was noted to be present in the appendix as early as the middle of the fourth month and thereafter in nearly every case it was present in the appendix till the end of fetal life. The amount of meconium in the appendix varies; it seems to depend somewhat on the condition of the cæcum—if the cæcum is distended then the appendix is always distended, but there may be meconium in the appendix while the cæcum is practically empty.

The Lancet, May 9, 1903.

The Treatment of Bubonic Plague by Yersin's Serum, with Observations on Its Mode of Action.—D. L. Cairns details his experience gained in the two recent outbreaks of plague in Glasgow. He believes himself warranted in stating (1) that Yersin's serum is a remedy of the greatest value in the treatment of bubonic plague; (2) that its action is bactercidal, as shown by the degeneration induced in the bacilli, as well as antitoxic; (3) that this double acton of the serum is best secured by its early administration in large doses, both subcutaneously into the lymphatic area which drains toward the bubo, and also intravenously; and (4) in very mild cases subcutaneous injection alone will probably suffice, but in severe cases the combined method should be employed. For these latter the initial combined dose should be perhaps from 150 to 300 c.c., the proportion given intravenously varying with the relative severity of the general symptoms.

The Position of the Heart in Some Cases of Aortic Aneurysm.—H. Walsham notes that in many instances of aortic aneurysm the transverse position assumed by the heart is of great diagnostic value—more important than the downward displacement giving rise to epigastric pulsation. The transverse position seems to raise rather than lower the apex beat unless there be considerable hypertrophy of the left ventricle, which in aortic aneurysm is quite the exception. The cause of the transverse position is the pushing of the heart by the superincumbent weight of the aneurysmal sac. In the absence of other positive physical signs this transverse position is of great diagnostic importance. Two illustrative clinical histories are added.

Acute Amaurosis Following Infantile Convulsions.—H. Ashby and S. Stephenson report five cases and then enter on a general discussion of the subject. Their conclusions are as follows: (1) There is a form of amaurosis which occurs in infants or young children which is post-eclamptic, due to anæsthesia of the visual centers. (2) The convulsions, which may be due to various causes, are apt to be severe and accompanied by coma. (3) The amaurosis may be associated with aphasia and paresis of hemiplegic distribution; the hemiplegia may be permanent. (4) The amaurosis is for the most part transient. It is possible that in some instances there is hemianopia.

Deutsche medicinishe Wochenschrift, April 23, 1903.

A New Stain for the Malarial Parasite.—Josef Koreck gives the following stain for the malarial parasite: Argentum methylene blue, 1 g.; aceton 2 g., distilled water 10 c.c., eosin 8 to 1.5 g. The argentum methylene blue is made by adding .5 g. of collargol to 100 c.c. of a 1 per cent. aqueous solution of methylene blue. The smear is fixed by any of the usual methods and submitted to the action of the stain for a varying length of time depending upon the age of the staining solution. If the latter has been freshly prepared nearly one half an hour is necessary, but if it has been allowed to age a much shorter time will suffice. In any given instance the proper time can only be ascertained by repeated trials. The advantage of the method is the sharp differentiation given by it between the red blood cells and the parasites, so that when the latter are ill defined with other methods they are plainly brought out by this one.

Münchener medicinische Wochenschrift, April 28, 1903.

The Estimation of Indol in the Fæces by the Means of Ehrlich's Dimethylamidobenzaldehyde Reaction.—Adolf Schmidt conducts these estimations by means of the spectroscope. A given amount of the dried fresh fæces are

submitted to Ehrlich's test in the usual manner. After the reaction is complete 1 c.c. of the tested mixture is submitted to spectroscopic examination when the characteristic absorption bands are seen. This is now diluted with sufficient alcohol to cause the bands to disappear, and the amount of alcohol so used is noted. By experimentation it has been ascertained that an indol solution just fails to produce its characteristic spectrum when it contains 1.25 mg. of this substance to the liter. Hence if the amount of fæces and alcohol used to produce the above result are known the computation of the quantity of indol in the amount of fæces tested becomes simple. From the figures thus obtained the amount of indol in the entire fæces is ascertained if the weight of the latter is known. For the accurate performance of this test it is absolutely essential that the fæces be fresh and thoroughly dried before using.

Berliner klinische Wochenschrift, April 23, 1903.

The Anti-tryptic Property of the Blood Serum in Croupous Pneumonia.—M. Ascoli and C. Bezzola show that in this disease the blood serum possesses anti-tryptic properties. These are at first not marked, but become much increased at the time of the crisis, remaining high for several days thereafter, and then gradually subsiding. Observation shows that the anti-tryptic properties are in all probability due to the destruction of large numbers of leucocytes, which is known to occur shortly before the crisis. The estimation of the anti-tryptic power of the serum is obtained by the addition of it in small quantities to gelatin which has been submitted to the action of trypsin, and noting its ability to prevent fluidification.

The Relation of the Presence of Glycogen in the Leucocytes to Infection.—Alfred Wolff, from a survey of the literature and his personal observations, concludes that the presence of the iodine reaction in leucocytes during infectious processes is a sign of a degenerated condition of these cells which is brought about extra- or intravascularly by the action of ferments or other causes. Such a degeneration is not always of a bacterial toxic nature, since in the presence of bacterial toxins the reaction is not always found. No casual relation exists between the iodine reaction and the phenomenon of leucocytosis.

The American Journal of the Medical Sciences, May, 1903.

A New Method of Connecting Flexion Deformity at the Knee-joint.—Royal Whitman, in his experience with a number of difficult cases of this class, conceived the idea of reversing the ordinary process of correction; that is, of making the femur the lever, and fixing the tibia, in order to avoid the danger of subluxation; for if a part is fixed it cannot be displaced. On the other hand, extension of the femur on the fixed tibia would tend to force its lower extremity backward, and thus to lessen the degree of subluxation, if it were present. The patient is anæsthetized and turned face downward upon the table. Pillows under the abdomen accommodate the deformity. The anterior surface of the tibia must rest evenly upon the table. The operator holds with one hand the head of the tibia firmly against the table, and with the ulnar border of the other begins forcible massage upon the contracted hamstrings, after the method employed in overcoming the resistance of the adductors in the operation of reduction of congenital dislocation of the hip. In this forcible massage pressure is begun half-way up the thigh, thus exerting a certain extending force. As the resistance lessens, the trunk is lowered and the assistant begins to press the thigh gently downward toward the table, rhythmically stretching and relaxing the resistant tissues, but never with sufficient force to lift the head of the tibia, which is firmly fixed to the table by the operator, reinforced, if necessary, by the hand of an assistant. If of long standing, and especially if subluxation is present, complete correction should not be attempted in one operation. Division of tendons may be required. A plaster bandage is applied after operation. This treatment is hardly necessary in flexion from simple muscular spasm. Certain cases are unsuitable for this or any other method of straightening. Osteotomy just above the joint is then advisable. The limb is then straightened.

Anatomical Study of a Short-limbed Dwarf, with Special Reference to Osteogenesis Imperfecta and Chondrodystrophia Fœtalis.—Ludwig Hektoen describes a fairly symmetric micromelic dwarf, aged forty-five years, presumably of fair intelligence, with a fibroid thyroid without any demonstrable thyroidin, with a relatively large cranial vault, made up of 172 Wormian bones, but without any evidence of premature ossification of the synchondroses at the base of the skull; with marked curvatures of the spinal column; with old fractures of many of the ribs and of the left humerus; with great deformity of the pelvis; with curvatures of most of the long bones, which are relatively short, the articular ends being swollen into irregular globular masses; with a general and pronounced osteoporosis; and with absence of trident fingers. Cretinism or rickets, or osteomalacia in all probability, is not wholly responsible for the changes present in the skeleton. As the matter now stands, final conclusion as to the cause of the condition found in this case seems unattainable, and it must be placed on record as one example of the grave changes that may be produced in the skeleton by obscure and interesting processes, the real cause and nature of which we do not understand.

A Contribution to the Study of the Human Blood-pressure in Some Pathological Conditions.—George William Norris states that: (1) Daily and hourly variations of tension are commoner and greater in amount than in health or in other afebrile pathological conditions unaccompanied by heart disease. (2) In mitral insufficiency the pressure is usually normal; it may be subnormal, but is rarely supernormal in uncomplicated cases. (3) In mitral stenosis tension tends to be higher than in insufficiency, and when both lesions are present it tends to be higher than when the latter condition alone exists, provided that compensation is fairly good. (4) In aortic insufficiency, especially if compensation is good, the systolic pressure is above normal, often markedly so. The wave amplitude is much greater than normal. The greatest amount of daily individual fluctuation occurs in this variety of heart disease. The pressure does not fall below the normal unless the lesion is complicated by mitral disease or myocarditis. (5) Myocarditis is usually accompanied by high tension, and cardiac dilatation by low tension. (6) No constant relation exists between pulse rate and blood-pressure.

Annals of Surgery, April, 1903.

Splenopexy for Wandering Spleen.—A case is reported by J. B. Hall, who makes use of the notch in the organ as a means of fixation. The method of operating in the case narrated is thus described: was the abdomen opened by an incision four inches long at the outer border of the left rectus abdominis. The lower pole of the spleen was exposed by this incision, and the whole organ was then delivered through it without much difficulty. It was seven and a half inches long and three and a half inches wide at its center. Except for its size, it was to all appearances a normal spleen. At this stage it was evident that splenectomy could be easily accomplished. The pedicle was so long that the delivery through the incision had scarcely tightened it, and the arrangement of the vessels was such as to allow of easy separate ligation. Whilst considering the advisability of removal, however, it was noticed that the notch on the anterior border was only two to three inches from the lower extremity of the spleen, and the depth of the notch was such that the lower pole of the spleen was only connected to the rest of the organ by a comparatively narrow isthmus. This arrangement at once suggested an easy means of fixing the organ. The main body of the spleen was therefore replaced in the abdomen after rendering the parietal peritoneum raw in the splenic fossa in order to excite adhesions. Then, whilst the lower pole was held in the wound, the edges of the peritoneum were drawn tight by a purse-string suture until they closely gripped the narrow isthmus in the notch. The abdominal aponeurosis was next sutured in a similar manner until it grasped the isthmus in the notch sufficiently tightly to produce marked congestion of the now isolated lower pole. The left rectus muscle was next drawn outward somewhat, so as to overlap the projecting pole of the spleen as much as possible, and the skin incision sutured. After closing the skin incision, a prominent lump the size of half an orange remained. The patient made a good recovery.

The Surgical Treatment of Anuria.—A. D. Bevan makes the following classification of cases: (1) Obstructive (urethral obstruction, unilateral or bilateral); (2) reflex or paralytic (unilateral ureteral obstruction suppressing function of opposite ureter by reflex action) removal of one kidney with suppression on the other side, hysterical and traumatic cases, and (3) non-obstructive or nephritic (inflammation of kidney, anæsthetics, poisons, toxins, urethral fever and lesions, gradually destroying one kidney and then the other (as tuberculosis, cystic degeneration, etc.). He offers the following suggestions: (1) The clinical importance of recognizing the three forms of anuria—obstructive, reflex and non-obstructive—is to be emphasized. (2) The imperative necessity of surgical interference in the obstructive and reflex forms, and its possible value in the non-obstructive cases. (3) In the first two varieties, at least, a rapid nephrotomy on the side of pain, tenderness, and muscular rigidity is the operation of choice. If necessary, do not hesitate to make a double nephrotomy. (4) Nitrous oxide anæsthesia is probably to be preferred. (5) Time-consuming operations to relieve permanently the obstruction are to be postponed to a later period, after the patient has recovered from the anuria. (6) We should operate early by the beginning of the third day.

Society Reports.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Sixth Triennial Meeting, Held in Washington, D. C., May 12, 13, and 14, 1903.

WILLIAM W. KEEN, M.D., OF PHILADELPHIA, PRESIDENT.

FIRST GENERAL SESSION, TUESDAY, MAY 12.

THE meeting was called to order by the President of the Congress in the Columbia theater at 3 P.M.

The Pancreas and Pancreatic Diseases.—This was the special subject for the afternoon's discussion.

Anatomy and Histology.—Dr. E. L. OPIE of Baltimore presented this, the opening paper. He said that the pancreas was provided with an accessory duct, which might take the place of the main duct when the latter was obstructed. The duodenal orifice of this accessory duct was excessively minute; during life it undoubtedly discharged its contents into the duct of Wirsung. Often the duodenal orifice of the accessory duct was obliterated. The speaker said that he had dissected the duct in one hundred subjects, and had found the two ducts present in every instance, although occasionally one or the other was so small as to be found with difficulty. In ten instances the two ducts failed to anastomose within the gland; in twenty instances the duodenal end of the duct of Santorini was not patent. In eleven specimens this duct was equal to or larger than the duct of Wirsung, so that it must have been the outlet for a large part of the pancreatic juice. He had found the head of the pancreas to be made up of two well-defined lobes. Out of 1,800 autopsies, in ten accessory pancreatic glands had been present. In two instances two accessory glands occurred in the same individual. The existence of more than one accessory gland could not be explained by the persistence of one or more embryonic structure; a more probable explanation was that at a very early period of embryonic life the lateral branch of the pancreatic duct was carried a variable distance from the pancreas and a new duct was formed. The cells forming the islands of Langerhans were found to have a common origin with that of the secreting acini. These islands were composed of columns of cells in intimate relation with a rich vascular supply. Two anatomical peculiarities of the pancreas had not yet received sufficient attention. In the first place, the organ consisted of two functionally diverse elements; on the one hand, cells supplying to the intestine important digestive ferments, and, on the other hand, cells having intercommunication with the ducts of the gland, but in intimate relation with the blood vessels. In the second place, the close relationship of the duct of the gland to the bile duct favored the transmission of morbid processes from the bile duct to the pancreatic passages.

The Physiology and Physiological Chemistry.—Prof. R. H. CHITTENDEN of New Haven discussed this topic. He said that it was well understood that the manufacture of the pancreatic juice was only one of the important functions of the pancreas. The closure of the duct of Wirsung caused no great harm; on the other hand, the removal of the entire gland resulted in a serious disturbance in carbohydrate metabolism. This was due to the fact that the pancreas had an internal secretion, and, therefore, belonged not merely to the digestive tract but to the whole chemistry of the blood and tissues. None of the other organs could vicariously step in and take up the functions of the pancreas. The secretion of the pancreatic juice appeared to be dependent upon the activity of the duodenal cells, another evidence that the functional activity of the gland was often dependent in no small degree upon the harmonious relation of some other structure. All physiologists were agreed at the present time that hyperglycæmia following the removal of the pancreas was due mainly to the inability of the organism to decompose the sugar formed in, or introduced into, the body, but as to the exact causes leading to this condition satisfactory proof was lacking. The cells of the pancreas had certain peculiarities of composition worthy of note. For instance, they contained more pentose than the other cells in the body. The pancreatic juice, like other digestive juices, was known to be modified in accordance with the nature of the food. In conclusion, the speaker called attention to the results obtained by Herter and others with regard to adrenalin glycosuria, and the reducing action upon the pancreatic cells. The fact that many organs of the body might form reducing substances capable of easy reduction, and which might reach the pancreas in the blood stream, made it probable that in this fact was to be found a new light on the origin of diabetes.

Etiology and Pathological Anatomy.—Dr. SIMON FLEXNER of Philadelphia, for lack of time, only discussed certain phases of this subject, particularly the acute and chronic inflammations of the pancreas, and fat necrosis. He said that a number of kinds of injury inflicted upon the pancreas, especially in dogs, set up a sort of hemorrhagic inflammation. If an irritating substance were thrown into the duct of the pancreas the pancreatic tissue would be injured, and this would be quickly followed by a hemorrhagic inflammation, which ordinarily terminated fatally. Solutions of chloride of zinc, of various acids and alkalies and solutions of bacterial growths, had been employed in this way. The same results followed the injection of gastric juice. Our knowledge of the etiology of hemorrhagic pancreatitis had been greatly advanced by the observations of Halsted and the experiments of Opie on the entrance of bile into the duct of Wirsung. It had a most important bearing on the etiology of hemorrhagic pancreatitis in man. Gangrenous pancreatitis was apparently a secondary condition engrafted, for the most part, upon hemorrhagic pancreatitis. The development of these hemorrhagic lesions were invariably associated with wide necrosis of areas of pancreatic tissue, and this should afford an excellent opportunity for the invasion and lodgment of putrefactive organisms derived from the intestine. Another series of pancreatic lesions had also been illuminated by experimental study. He had found that in dogs in which pancreatitis had been set up by the injection of gastric juice recovery sometimes occurred, and that later on cysts and other lesions in the pancreas were found which were apparently the result of suppuration within the gland. This seemed to support clinical observation. With regard to fat necrosis, the speaker said that certain circumscribed areas of fat necrosis of very variable size developed in the abdominal cavity under certain conditions, and their close relationship to the pancreas had long been suspected. This relationship had been demonstrated to exist by Langerhans, and more recent observation seemed to indicate that these areas were due to the presence of some of the pancreatic secretion and of a fat-splitting ferment. It was possible to prove by chemical tests that the fat-splitting ferment was there present. These fat necroses could be produced not only by perverting the secretion of the pancreas, but, as had been shown by Dr. Wells of Chicago, by introducing into the abdomen of animals some of the commercial extracts of pancreas, the so-called pancreatin. Dr. Opie had made out clearly two forms of chronic inflammation of the pancreas, an interlobular and an interacinar form, and the latter form was the one associated with diabetes. This fact had been confirmed by the observation of a great many cases.

The Symptomatology and Diagnosis.—Dr. REGINALD H. FITZ of Boston spoke on this topic. He said that morbid changes of the pancreas were frequently found after death without symptoms pointing to such lesions having existed in life. The lesions occuring in the pancreas in conjunction with diabetes were those of interstitial inflammation with corresponding destruction of

the parenchma of the pancreas; nevertheless extensive destruction of the pancreas sometimes occurred without observable modification of its function. The destruction of the islands of Langerhans in cases in which gross examination showed no extensive involvement of the pancreas, explained the occurrence of diabetes in such cases. Bronzing of the skin and enlargement of the liver without jaundice or the pigmentation of Addison's disease, pointed to chronic fibrous pancreatitis. With regard to steatarea the speaker said that a table of twenty-nine cases had been prepared to show the relation between visible fecal fat, jaundice and pancreatic disease. This table showed that jaundice was present in twelve cases and diabetes in eleven cases, suggesting that in about three-fifths of the cases of steatarea attributable to pancreatic disease, neither diabetes nor jaundice was an important factor. The author's conclusion from this study was that steatarea should be attributed to pancreatic disease only when other causes of this condition could be excluded, the most important of which was interference with the flow of bile into the intestine. It had been repeatedly noted that fecal fat had been present when persons were eating an abundance of fat; hence it was important to eliminate this possible source of error. The capacity of the patient for digesting fat and for digesting muscle fiber should be tested, having first determined the condition of the gastric functions. The possibility of testing the efficiency of the pancreas by the attempt to produce an artificial glycosuria was worthy of consideration, though there were so many conflicting factors that, at the present time, it could hardly be considered of much diagnostic aid. The examination of the urine for pentose had attracted attention. It was possible by this test to find crystals of phenylhydrazin in normal urine. The quantity of the ethereal sulphate gave some indication of the extent of intestinal putrefaction and of the secretion of pancreatic juice. Herter had found increase of indican and of the preformed sulphates in Northrup's case of malignant disease of the pancreas. Opie had suggested the possibility of finding in the urine the fat-splitting ferment. The differential diagnosis lay between acute and chronic affections, and between several varieties of pancreatic disease. The symptoms of acute pancreatitis were essentially those of peritonitis developing in the epigastrium suddenly in persons apparently in perfect health. Exploratory laparotomy had proved the most satisfactory method of treatment. The diagnosis of chronic pancreatitis was usually based on the occurrence of localized pain and the presence of a tumor.

Surgery of the Pancreas.—Prof. Von Mikulicz-Radecki of Breslau, Germany, presented the first paper on this part of the general subject, discussing injuries and inflammatory processes. He said that the operative measures for exposing the pancreas were of two kinds, the transperitoneal and the retroperitoneal. The last-named method aimed to reach the pancreas by an incision in the lumbar region. The advance of pancreatic surgery had been greatly hindered by the difficulties of diagnosis. The surgeon could not usually rely upon the signs of functional disturbance because these ordinarily did not appear until the greater part of the gland was already diseased. Another difficulty encountered in the surgery of this region was the great danger attendant upon operation on this gland. Deeply buried sutures must be used in order to control the hemorrhage, and yet this very procedure favored necrosis and, moreover, did not always prevent the occurrence of secondary hemorrhage into the peritoneal cavity. A special danger was the leaking of the pancreatic secretion. This seriously affected the peritoneum and the neighboring tissue. In ninety-one cases of resection of the stomach in which the pancreas was certainly not injured, twenty-seven died as a result of the operation. In thirty other cases, the pancreas was injured, and of these twenty-one, or 70 per cent., died, usually of peritonitis. In the majority of cases the secretion from the pancreas acted indirectly by causing local irritation of the peritoneum and by affording an excellent medium for infection. The injured part of the pancreas could be turned inward and closed with sutures so as to prevent such leakage into the peritoneum, but usually it was necessary to protect the parts by means of tampon drainage. Of eight cases of injury of the pancreas, treated by such drainage, six recovered. Wherever pancreatic tissue had been exposed the abdominal cavity should be tamponed and drained. Statistics were quoted to show that severe injuries of the pancreas, if not subjected to operation, terminated fatally almost without exception, and also to emphasize the need for exploratory laparotomy when there was reason to suspect injury of this organ. Most surgeons were opposed to early operation in acute pancreatitis. He believed the great majority of these patients died in the acute stage, so that it was possible that better results would follow an early and rational operation. Chronic pancreatitis should always be considered when making a diagnosis of cholelithiasis and *vice versa*. The results of operation in chronic pancreatitis were very encouraging.

Tumors and Cysts of the Pancreas.—Dr. Roswell Park of Buffalo treated of this part of the subject. He said that the cysts met with were: retention, proliferation, hemorrhagic, hydatid, congenital and peripancreatic or pseudo-cysts. The proliferating cysts sometimes evinced malignancy. Most of the hemorrhagic cysts were examples of hemorrhages taking place in cysts. The escape of blood and pancreatic juice into the peritoneum might very easily give rise to a tumor which, in the living subject, might be almost indistinguishable from a true cyst. Fistulæ resulting from these operations had proved most obstinate. Aspiration had nothing to recommend it. The treatment should be by incision, and posterior drainage would often prove a time-saving measure. Cancer was especially common in the head of the pancreas, and often reached a considerable size. The symptoms were far from definite. When there was a well-founded suspicion of a tumor of the pancreas an operation should be undertaken.

Dr. Charles G. Stockton of Buffalo opened the general discussion. He said that there seemed to be still reason to believe that diabetes might exist without ascertainable disease of the pancreas. The question of polyuria should not be overlooked. In cases of achylia gastrica, in which there was a disappearance of the gastric juice, including the hydrochloric acid, intestinal digestion did not appear to be affected, a point of some interest in connection with the statement that had been made, that the pouring out of the acid gastric juice into the duodenum was the normal stimulus to the secretion of pancreatic juice.

Dr. Herbert U. Williams of Buffalo said that it was very easy to determine in a moment, by the microscope, the nature of the areas formed by fat necrosis. Not enough attention had been paid to the work of Chiari on self-digestion of the pancreas. It was not uncommon to find at autopsies areas of fat necrosis, sometimes associated with hemorrhage, and he could see no difference between them and those observed in acute pancreatitis, except in degree.

Dr. Maurice H. Richardson of Boston said that at the Massachusetts General Hospital out of upward of seven thousand abdominal operations there had been only seven done for acute pancreatitis. In his experience the disease had been seldom diagnosticated before operation, and the lesion had usually occurred rather late in life in stout persons of poor physique. Acute infection compromising the whole gland permitted only of drainage and this did not check the progress of the necrosis; hence, operation was often only a forlorn hope. The surgery of benign new growths of the pancreas seemed to have a brilliant future. It was chiefly in the treatment of

aseptic lesions of the pancreas that surgery had an encouraging though limited field.

Mr. B. S. A. Moynihan of Leeds, England, being invited to speak, reported two very interesting cases, and spoke in flattering terms of the excellent original work in this field done by Americans, particularly Flexner and Opie

President's Address: "The Duties and Responsibilities of Trustees of Medical Institutions."—On the evening of the first day of the Congress a large audience assembled to hear the President's address. Dr. William W. Keen took the above for his theme. Speaking of medical colleges, he said that one of the best means of promoting harmony among the faculty and the trustees was by the latter inviting the former to be present, in a purely advisory capacity, at the board meetings. He was firmly convinced that the best interests of all concerned demanded that medical teachers and members of hospital staffs should be retired by a standing rule at the age of sixty-five years, because while admitting that some men were in full possession of their faculties at that age, and their retirement would be a loss to the institution with which they were connected, there were a score of instances for one of those just mentioned in which the retention of men at this age was greatly to the detriment of the institution. It was advisable to have a small proportion—not over 20 per cent.—of well-chosen medical men on the board of directors of a hospital, but these men should be selected for their large mental caliber and great executive ability. The remainder of the address was an earnest and eloquent plea for the best modern equipment of hospitals and a free use of patients for clinical teaching. After an experience of forty years in hospital work, he could say that he had never seen a patient injured by such teaching, and it was an excellent training for the staff, for students were the best possible whip and spurs to good, careful work.

ASSOCIATION OF AMERICAN PHYSICIANS.

First Day—Tuesday, May 12.

The President's Address.—Dr. James Stewart of Montreal contrasted the progress of the society from its inception in 1886 up to the present day, showing the marked improvement in the character of the papers read as time had gone on until now they have reached that degree of excellence when most of the papers read were of a true scientific value. In closing, Dr. Stewart felt it his duty to pay tribute to those members of the society who had died during the past year. They were: Dr. White Johnson of Montreal who had succumbed to septic poisoning; Dr. Fred Packard of Philadelphia of typhoid fever, and Major Walter Reed, who died as a result of an attack of appendicitis, November 23, 1902.

Bathycardia (low heart).—Dr. E. G. Janeway of New York read this paper. Two cases had come up recently in the doctor's practice in which a heart had been displaced downward, due to an elongation of the arch of the aorta. No disease could be demonstrated to be present below the diaphragm, which might account for the conditions present in these cases. This condition was not hard to recogni e. The signs were: lowered position, absence of cardiac dulness at the base with the apex in the sixth interspace, at times hard to demonstrate. Flatulence was liable to increase the distress in these cases; depression of the liver was not a marked sign in these cases.

Dr. Mossler was the first to describe this condition. The fluoroscope gave a satisfactory result on examination. There has been no autopsies reported in this condition. These patients always had long, flat chests.

Dr. Osler of Baltimore said that in cases of hypertrophy of the right ventrical there may be a bulging in the parasternal line which might be taken for an aneurysm. He had examined many cases of enteroptosis, but had found in them no descent of the heart from its normal position.

Post-typhoid Sepsis.—Dr. Francis Delafield of New York read this paper. In cases of typhoid fever, after the fourth week there had often been noticed a fever which was not typhoid, unless there was a relapse. Of course, there might be an infection of the bladder and other organs due to the typhoid bacillus, but in reality this was not a typhoid fever, but a true septic fever, due to the presence of the germ of typhoid. Most cases of relapse in typhoid fever took place in from three to twenty-five days after the symptoms of typhoid had disappeared. One relapse was common; a second relapse was comparatively rare. Post-typhoidal fevers owed their origin to three causes: first, the ordinary rise of temperature, which continued after the typhoid symptoms had defervested, and in the second week following the typhoid infection. These were due to asthenia. Secondly, those of importance which lasted two weeks, where it was necessary to give the patient solid food and get him out of bed. The temperature might be continuous with that of typhoid, or after an interval of three days it might rise. In these cases there was no delirium, no eruption, and no tympanites. Not a few of these had heart collapses, but in the end they would get well, provided they were taken out of bed and properly fed. This sort of fever might run to a 103° F., or even as high as 107°, with chills. There might be a severe and long-continued fever, which might terminate fatally. These occurred four weeks after the inception of the fever, and were true cases of septic fever, the morning temperature being 100°, and the evening temperature perhaps as high as 103°. There might be intervals of one or more days, and then a chill. These patients looked septic and were septic; the mind was often dull, but there was never delirium; there might be thrombosis of one or both femorals. Autopsies showed the cause of death to be sepsis and starvation. These patients should be taken out of bed and fed, when they would gain flesh in a most rapid and astonishing method. One of the office cases had gained twenty pounds in the space of ten days. In the end of typhoid there might come on an infection so severe as to resemble streptococcus invasion. These also called for solid food and exercise.

Dr. Henry Koplik of New York said it was common to have, after the fourth week, a slight rise of temperature for two or three days in children between the ages of three and twelve. Although they might be emaciated and run down after five or six weeks infection with a continuous temperature, he had always made it a practice to take the children out of bed and give them solid food. Recovery had followed in all of his cases in which this condition and method of treatment had been employed. He regarded this sort of a fever as one of inanition, or as the result of septic absorption from the intestines.

Artificial Immunity in Experimental Tuberculosis.—Dr. E. L. Trudeau of Saranac Lake, N. Y., read this paper. There were three kinds of immunity—natural, acquired, and artificial. Artificial immunity was present very often after injection of living germs, but there was also present in many of these cases a secondary infecton which massed the artificial immunity which had been set up. In acute miliary tuberculosis the bacillus was hard to find, possibly due to the fact that an artificial immunity had been acquired. Artificial immunity was present in 60 per cent. autopsies, as shown by healing in a great many cases, but we should discriminate between a healed and an arrested condition. Of course, there were the toxin and bacterial immunities; the first was obtained by the production of an antitoxin in the blood serum by means of previously prepared blood sera in other animals. The second was induced by the injection of the living germs into the living organisms. Koch's tuberculin did not protect against the living tubercle bacillus. Success in immunity was only obtained from the injection of living

tubercle bacillus. This was called Behring Isopathic Immunity. Rabbits could be inoculated and rendered immune by the injection of attenuated bacilli. Prolonged cultivation through media and animals produced attentuation of the tubercle bacilli. The essayist showed a culture, eleven years old, which was so attentuated that it could not kill rabbits. After six years guinea-pigs, which were especially susceptible to tuberculosis, could overcome the effects of inoculation. Vaccinated animals lived three times as long as those unprotected. Immunity produced by continued inoculation until rabbits did not react to the tuberculin, was the best form of immunity that had so far been accomplished. In protected animals, in whom inoculation had been practised, the infected area healed very slowly after a long time. There was formed a specific substance in the blood serum of a calf which had been immunized, but this specific substance was only protected for a period lasting over three months. Intravenous injection of attenuated cultures did not affect the lungs of rabbits after fifty days. Inoculation of virulent bacilli after 104 days in immunized rabbits produced no results in the lungs, except those which were present in chronic tuberculosis of the lungs, and these lesions had healed and defervesced after a short period of time

Studies in Mammalian Tuberculosis III, Description of a Bovine Bacillus for Man: Culture Tests for Distinguishing the Bovine from the Human Type of Bacilli.—Dr. Theobald Smith of Boston read this paper. Two points of interest were brought out in this paper: first, in 1896 the essayist had called the attention of the medical fraternity to the difference in variance of two bacilli, one in man, the other in cattle. These two were of different varieties, and were distinguished very readily by their morphologic, biologic and characters of virulence, such as methods of growth, etc. The one was called bovine, the other the human tubercle bacillus. The author had had two cases of tuberculous involvement of the mesenteric glands of children, in which the disease had evidently entered the intestines through the mucous membrane in the same manner in which bovine tuberculosis affected cattle. One of these bacilli grew with difficulty, while the other very readily grew on all the recognized media for their culture. One the author determined to be a human variety, and the other the bovine. These cultures were injected into two separate animals; the human did no harm, while the other rapidly destroyed the subject after a short space of time. The human bacillus was really an attenuated culture. In both of these bacilli there was present, after two months, a difference in their reaction toward litmus paper. The bovine showed a slow diminution from the acid to the alkaline reaction, whereas the human started with the alkaline and slowly became acid.

Not all cases of mesenteric involvement were due to bovine tuberculosis. In conclusion, the author said that bovine tuberculosis could pass through man and that involvement of the human subject with the bovine bacillus was rare.

Dr. Osler asked if there were any difference in the microscopic appearance of the mesenteric glands of bovine and human infection.

Dr. Smith answered that the bovine contained an enormous number of tubercle bacilli, and that none was found in the human glands.

Dr. Osler remarked that the lymphatic type should be more carefully looked into to see whether or not it were closely allied to bovine tuberculosis.

The Transmission of Bovine Tuberculosis by Milk.—Dr. George M. Kober of Washington, D. C., read this paper. Cases of primary instances of tuberculosis, as a result of infection through the ingestion of milk into the intestinal track, were rare, hence it was of no importance to take into consideration the transmission of bovine tuberculosis by means of milk ingestion. This was the opinion of the profession at large, but the author had succeeded in tabulating eighty-six cases of milk-borne infection of bovine tuberculosis. Carmichael, in forty-nine cases, showed that children were prone to bovine infection after weaning. Scrofula in the children of Paris had been very easily attributed to the tuberculosis in cows, as statistics of that city showed that their cattle were most commonly infected with this disease. These children were known to have been infected, especially during that period of life when milk occupied the most important place on their list of diet. The author's conclusion was that tuberculosis might be transmitted from animals to the human subject. This had been established by feeding experiments, and by the accidental infection of those working about the cattle. The author supported Theobald Smith's idea that there were two varieties of the tubercle bacilli. An interesting observation had been made which showed that the phosphates in tubercular-infected cows were more than seven times greater than in the normal healthy animal, and that this increase was probably due to the activity of the tubercle bacillus.

Dr. Trudeau remarked that Behring had succeeded in protecting cows from bovine tuberculosis by previously immunizing them with avian tuberculosis.

Dr. Smith said there was a certain adaptation of species, as in families and races, but that this should not be put down as an argument against the existence of the two varieties of the bacillus. The difference of reaction of these bacilli, of which he had spoken, to gelatin was sufficient to class them as separate and distinct varieties, and that a unity could not be made because of the existence of reciprocal immunizing properties.

Primary Tuberculosis of the Tonsil: The Tonsil as a Portal of Tuberculous Infection.—Dr. Henry Koplik of New York read this paper. He said that the tonsil was very rarely the seat of primary tuberculosis, especially when there was no other seat or focus of tuberculosis to be demonstrated in some other portion of the body. Primary tuberculosis with involvement of the glands was present in a limited number of instances; secondary involvement of the tonsils was common. Infection of the lymph nodes was frequent in children and, if primary, gave a favorable prognosis after operation. The tonsil might be absolutely normal, but a great number of them were hypertrophied. Hypertrophied tonsils in children were often infected by tuberculosis in some form or other. There was no reason why the tonsils should not be the portals for the entrance of the tubercle bacillus, but it was hard to show how this infection might take place; possibly the germ was introduced into the tonsillar tissue during the act of deglutition (Kohnheim). The author reported a case of general infection caused by the spread of the disease, which had entered through the tonsils. This case had been secondary to the involvement of the tonsil by a diphtheritic membrane.

A Skin Lesion Associated with the Rapid Growth of Long Bones (Les Vergetures de Croissance, Jules Comby).—Dr. W. P. Northrup of New York read this paper, saying that such conditions as he was to describe in his paper were very rare in literature. He could best describe the lesion as being identical with the lineæ albicantes which were so often seen on the abdomen of parturient women. An adult male was the patient who had been infected. He had come of a tall family, and had always been a healthy man. At the age of seventeen years he was of the average height, but at this time, was attacked by a typhoid fever. During the time he was in bed he evidently grew some, but for two years after the attack of typhoid fever everyone remarked how rapidly and steadily he was growing. The scars had not been present previous to the typhoid fever. Some authors had remarked that this condition was present in all acute and chronic febrile diseases which compelled the child to remain in the horizontal position at that period of life corresponding to the maximum growth, and that such children were known to grow as much as

5 c.m. in two weeks. Skin lesions over the patella were present in this case; they varied in number from twenty to fifty on the various sides of the joints. It would seem that the skin did not keep pace with the growth of the long bone; hence it was forced to stretch and lose its continuity in appearance.

Dr. Abram Jacobi of New York remarked that the cases reported were but exaggerations of a condition most common in children, following typhoidal infections, and that they were due epiphyseal hyperæmia, and were the reverse of the condition present in rickets.

Dr. Osler of Baltimore had seen these striæ in the cases of adults following typhoid fever.

Visceral Lesions of the Erythema Group of Skin Diseases (Third Series).—Dr. Wm. Osler of Baltimore read this paper by title.

Dermato-myositis.—Dr. F. Forschheimer of Cincinnati read this paper, reporting a case of the same conditions. The patient was a female aged forty years, and of a neurotic temperament. In 1899 the patient complained of an eruption on various portions of the body. In 1901, suddenly after the death of a brother, she lost all her nerve force, and since that time had suffered with irritability of the skin and mucous membranes. In the fall of this year a fistula had developed on her arm, and later various others on different portions of the body. Soon after the first pustule the patient was compelled to go to bed. At this time her left leg became swollen down as far as the ankle, but there was no pain present so long as the member was kept at rest. Four days later the same conditions of swelling and pain on movement took place in the right thigh. The pain was especially exaggerated by movement of the rectus muscle, and there were also present general hyperæsthesia and sleeplessness. Electric tests, following the attack, showed that there was present an atrophy of certain muscles. Pfeiffer had reported twelve cases of this kind and Lawrence three more. Pleyhn showed that the disease was not progressive, and that the symptoms in general had been made out by him, along with Lawrence, to be fever, enlargement of the spleen, involvement of the long muscles and those of the tongue, while the muscles of deglutition and the diaphragm were not included in the condition. There were also present an erysipaloid eruption and profuse sweats.

Observations upon Results Obtained in Infant Feeding, with Various Forms of Milk in Tenements and Institutions in New York.—Dr. L. Emmett Holt and Wm. H. Park of New York read this paper. The contents of this paper, in general, were that the various forms of milk upon which the infants of the lower East side of New York were fed resulted in diseased conditions only when the milk was bad. The goodness and badness of the milk consisted in the presence or absence of bacteria and chemical constituents which caused coagulation of the substances contained in the milk. The milks that were used were ordinary grocery store milks, condensed milk, milk from the distributing stations, and the high-class bottled milk. Contrary to the general idea, the majority of the tenement-house children were not bottle-fed; inquiry showed that not more than two or three children on a block received their nourishment from bottles, and that in a large majority of the cases some form of sterilization was practised by the mothers. Results showed, in a number of cases which had been selected and carefully followed, that in the summer time 68 per cent. was good, and 32 per cent. bad; in winter the good results amounted to 93 per cent. By results "good" and "bad" was meant the outcome of feeding on these various forms of milk at regular stated intervals, laid down by twelve selected physicians who had the supervision of the cases under observation. Curiously enough, the bad results obtained with condensed milk were not due to bacteria, because condensed milk was free from bacteria, and the water with which it was prepared was usually previously boiled. The Strauss milk in winter gave the best results, as it also did in summer time. Milk preserved with 1-20,000 gave quite severe gastric disturbances in some instances, but in good milk it did not impair the functions, and in bad milk it did no good. The conclusions arrived at by the investigators were that the feeding of infants was a most complex question in tenement-houses; that it depended for good results upon cleanliness both in preparation of the food and of the food itself, and also upon the good attention which the patients received. A most important factor was to be found in the proper dispensing of the milk to these patients, which would best be carried out by the establishment of dispensing stations where the milk could be properly prepared and rational instruction given the mothers in regard to the nursing and feeding of their babies.

AMERICAN SURGICAL ASSOCIATION.

First Day—May 12.

The address of the President, Dr. Morris H. Richardson of Boston, was entitled "The Contributions of Surgery to Internal Medicine." Dr. Richardson spoke of the difficulty of interpreting living conditions from the dead, even in the rather unforeseen event of autopsy being allowed. This was particularly to be noted in appendicular and gallstone surgery. Again, even in the event of being able to obtain a necropsy, it has frequently been shown that the first post-mortem interpretation of conditions might be absolutely incorrect, so much so, as to lead to the possibility of fatal errors based upon a technique derived from such findings. Surgery had taught the internist the reason for symptoms; what constituted the normal and what the abnormal position of the viscera. The author cited a number of cases at this point in which he had opportunity at the time of operation to study and observe the variabilty in the position of the lower line of the stomach in young active subjects upon whom he was operating for the repair of perforating wounds. Nor did he assume that the stomach was the only viscus in which this variation of position without the presence of symptoms resulting from it, because there was ample ground for believing that the liver and other viscera frequently varied in like manner. It was only at the operating table that such problems could be answered, and inasmuch as surgery was now so safe, it would seem that the internist must at last yield to the demands of the surgeon and be given the undeniable boom of a positive diagnosis from his hands. There was nothing more important in these conjectures than the relation of the physical signs which existed before the operation, and those found as a result of exploration, because by the amassing of a countless number of such data we should eventually be able to establish diagnosis without abdominal section, which to-day were impossible. To this end it became necessary for the surgeon to make a most thorough and conscientious physical examination of every patient, both for the sake of the impending operation and its result, as well as for that of future work. It would not be long before most abdominal lesions would fall into the category now occupied by the gall-bladder and the appendix, which were now so generally recognized as purely surgical diseases.

The Toilette of the Peritoneum in Appendicitis.—Dr. George R. Fowler of Brooklyn read this paper. He spoke first of those conditions in which the peritonitis was confined to the appendix, and subdivided this according to the presence or absence of adhesions of pus. The other group upon which he dwelt was that in which there was a general infection of the peritoneum. This should be treated by a pre-removal of the primary source of infection. He would irrigate the region by the use of tubes which are so arranged that the flow of the water is toward the lumen rather than away from it. Several

gallons of this solution should thus be used, and in occasional cases drainage through the tank might prove of value. Under any conditions he deemed the saturating of all gauze used in these cases in which pus might flow, with one to 2,000 bichloride an admirable and life-saving technique, because if any pus chanced to leak through the gauze and thence into the cavity of the peritoneum, it would be less septic after it had been exposed to the mercury than without it. In those cases which were diffusedly sceptic, he advised local cleaning, but considered even eventration and scouring as most unsurgical. For drainage, glass or smooth rubber tubes were much preferable to gauze.

Operations upon the Stomach with Special Reference to the Toilette of the Peritoneum.—Dr. A. Vanderveer of Albany said that the importance of this topic had grown with the progress of success of operations upon the stomach. This had forced upon him long ago the conclusion that an avoidance of excessive traumatism, or, indeed, even of the slightest injury to the peritoneum was of paramount importance, both for the immediate as well as for the subsequent success of the case; thus it became necessary to determine means of establishing positive diagnosis, because only by such accuracy would it be possible to inflict the minor injury upon the peritoneum. Naturally the first step in this procedure consisted in making as small a wound as possible. As the operation advanced, it became desirable to avoid soiling the peritoneum by any fluids of the body with the possible exception of blood or healthy bile, because all the aforenamed acted as pronounced irritants. Along the same lines he felt it desirable to use even the bland and non-irritating salt-solution with the very greatest care. The peritoneum should be treated, he said, as a friend, and thus, as in the case of friendship, one should not overreach or overdo the friend's obligations, so with the peritoneum, if one expected to get the kind return from it which good treatment would assure, it must be treated with the most deferential respect.

Toilette of the Peritoneum in Tuberculous Peritonitis.—Dr. A. J. Ochsner of Chicago read this paper. He said that the literature showed a truly marvellous proportion of recoveries in apparently hopeless cases arising from this condition. In his own hospital there were frequently brought in patients almost moribund, with abdomens so tremendously distended that the diagnosis could not be made. Years ago he, in company with others, had been in the habit of merely opening them, possibly inserting a drain, for a time and letting well enough alone. Later on, however, the aggressive surgical rapacity of the times had prevented him from playing so passive a part, and he, with others, had attempted and executed the resection of as much of the tuberculous material as was possible. Some five years ago he noticed that whereas in the old days all the cases got well, under the modern method of treatment all died. He therefore concluded, from a study of forty cases, that those in which there was the greatest amount of exudate were the most hopeful that great care should be used in making intraabdominal investigation in order to produce the least possible degree of traumatism, because undoubtedly many died from miliary tuberculosis as a result of such minor wound; that the manipulation of the infected ovaries and uterus was less harmful than that of diseased intestine

On Septic Phlebitis of the Roots of the Portal Vein and on Pylephlebitis, Together with Some Remarks on the So-called Peritoneal Sepsis.—Dr. Arpad A. Gerster of New York said that this interesting and little understood condition was in many cases caused by detachment of emboli of the feeders of the portal vein, and that appendicitis was the most frequent etiological factor. The condition, unrecognized and untreated, was preëminently fatal, it being probably the gravest of all possible complications. The gross pathology of the disorder consisted in the formation sometimes of continuous thrombi of a resisting and elastic-like texture or in a series of interrupted or continuous thrombi of a tubular pipe-like type which were often found to be filled with seropurulent secretion. Because of the anatomical arrangement of the region, the portal vein was peculiarly subjected to all sorts of greater and lesser traumata, which naturally were prone to dislodge portions of the thrombi. Most important of these he considered to be muscular violence. The recti-muscles in the act, for instance, of coughing, might easily create such pressure as to drive emboli into the liver. Depending entirely upon the character of the thrombi and upon the nature of the circulation in the liver, which undoubtedly varied somewhat in different individuals, death might be caused by a filtration through the organ and into the systemic veins of toxins, of bacteria or even of grosser products. He believed that under the latter conditions pulmonary embolism might ensue from portal thrombosis. The conditions introduced depended naturally not alone upon the anatomical conditions presented, but upon the amount and virulence of the organisms or their products which were injected into the system. In this most instructive manner, he explained the death of patients who were operated upon by competent surgeons by apparently faultless techniques. In these appalling cases, the complication was brought about by the fact that in the previous one or two attacks of acute appendicitis which they had had, the portal system had undergone in a portion of its path thrombotic formation, and these by the manipulation of the surgeon at the time of the interval operation were dislodged, passed into and through the liver to kill the patient by fulminating sepsis.

The Toilette of the Peritoneum in Appendicitis.—Dr R. H. Harte of Philadelphia read this paper: He said that the frightful gravity of the condition, the extreme prostration and weakness of the patient at the time of operation demanded the most thorough and rapid technique. Fortunately for the future of the operation, it was now well established that over 90 per cent. of the perforations occurred in the ilium within twenty-five inches of its junction of the cæcum. An observance of this rule had enabled operators, by making their incision in the right rectus below the umbilicus, to reduce their mortality from over seventy to a trifle over sixty per cent. So certain was this rule in its application that an operator would be justified in maintaining that a mistake in diagnosis as to perforation had been made if no signs of peritonitis presented themselves either over the cæcum, the ascending colon or the last two feet of the ilium. The lesions in themselves were usually exceedingly small and hard to find and it was therefore a great step in advance to know positively the territory to which they were habitually limited. He advised a simple and rapid infolding of the part by a quilted Lembert stitch, all dark necrotic spots being treated as though perforated. It was rare that the perforations were large enough to make it possible for such infoldings to interfere with the lumen of the gut. But in the event of such being the case, it was desirable to simply sew the gut to the belly wall, thus making an ileosotomy or colostomy as the case might be rather than to attempt a resection of the part. Evicceration he considered most dangerous as a means of treating extravasation and peritonitis, regarding thorough irrigation and drainage as much to be preferred. So far as this part of the technique went, it was axiomatic that the operation itself should be done with all possible speed, whereas the irrigation should be continued as long as might be necessary to remove all particles of extravasated material and to leave a free amount of normal salt-solution in the cavity.

Toilette of the Peritoneum in Typhoid Operations.—Dr. S. H. Weeks of Portland, Me., readthe conclusions of his paper only. He said first that no one method was suitable for all cases; that, of course, in the absence of pus

no drainage was necessary. In circumscribed pus cavities, irrigation should be used, but the utmost gentleness must be employed in its exhibition lest the adhesions be broken. It was then customary with him to pack the cavity with sterile gauze. A number of his cases in which he had formerly neglected to search for concretions had been obliged to undergo a secondary operation for the recovery of these masses. He therefore deemed it of very great importance to remove them during the primary operation. In the event of finding the intestines floating in a sea of pus, he had come to the conclusion that the employment of thorough irrigation with hot saline solution was better than wiping the parts with dry gauze.

Toilette of the Peritoneum in Gunshot Wounds of the Stomach and Intestines.—Dr. Tully Vaughan of Washington, D. C., presented this paper: He said that there were two distinct classes in which drainage was indicated. The first were free from peritonitis. One group under this class had not suffered from the extravasation of visceral contents; another group had; while in the third group the extravasation was hemorrhagic in character. The second class considered embraced those in which peritonitis had developed and it might conveniently be subdivided into those groups where the lesion was local and where it was general.

The Treatment of the Peritoneum in Spreading and Diffuse Peritonitis.—Dr. Joseph A. Blake of New York read this paper. He divided the conditions as follows: (1) into abscess with the formation of adhesions; (2) into abscess formation without limiting adhesions; namely, spreading, but yet not entirely involving the peritoneum; (3) the entire involvement of the peritoneum. There were two important principles, he said, which should guide in the treatment of these conditions, viz., the removal of the nidus and an effort to help the peritoneum to withstand the infection. Obviously an early operation was the best and only means of accomplishing this end. The subject of drainage divides itself into two classes, viz., those in which the cause can be removed, and, second, all others. Drains, he said, were not by any means ideal, for no matter what type one employed, they might lead to the formation of intestinal obstruction of a transient or permanent type. The varying positions of exudates could not be accounted for by gravity alone, and were, perhaps, to be explained in part by the suction action of the diaphragm. Years ago he had been in the habit of instituting the freest kind of drainage in these cases, but lately he had come to the conclusion that too much had been done along these lines. In support of this position, he related that in a large number of cases which had survived, the period of convalescence had been eighteen days shorter in those in whom there had been no drainage. Furthermore these cases reached a normal temperature in six days, whereas those which he had drained, had an elevated reading for twelve days. His résumé of treatment consisted in advocating early operation, free and copious lavage, and closure without drainage whenever practicable.

In the discussion of these papers, Dr. Munro of Boston said that he was unable to agree with Dr. Gerster as to the rarity of the cases which he had so ably described, because in Boston, they had found a much larger proportion than Dr. Gerster. Perhaps the reason for this lay in the fact that they expected to find the thrombosis of the portal vein in cases of subacute rather than in the so-called interval class. He held the retroperitoneal lymphatics to be responsible for a majority of the deaths rather than the liver. In support of this he said that the liver was rarely enlarged, which it would be fair to expect it to be in the event of its transmitting a fatal toxæmia or bacteræmia to the system. He agreed with the author that spontaneous cure was possible in portal phlebitis, but added that in his opinion it was frequently associated with retroperitoneal lymphangitis.

Dr. Gerster, in closing, advised a splitting of the veins and a turning out of all thrombi. This constituted the new and important addition to the toilette of the peritoneum which he desired to make.

Subdural Implantation of Rubber Tissue in Operation for Inveterate Neuralgia of the Fifth Pair, without Removal of the Gasserian Ganglion.—Dr. Robert Abbe of New York read this paper. He said that it was now proven beyond a doubt that all operations upon the extremities of the three divisions of the fifth nerve were of such short-lived value to the patient that their justification and employment had become with him a thing of the past. In like manner, he had years ago made up his mind that the disease, save possibly in the rarest of cases, lay not in the ganglion itself, but was actually a neuritis of the deepest portions of the nerve trunks. He had, it was true, resected the ganglion with most admirable results, but the danger to the patient from the hemorrhage, which might be most appalling, together with the high mortality which his autopsies had shown him to arise from the laceration and compression of the frontal lobe at the time of the operation had made him hesitate to continue. Accordingly, acting upon the belief that the lesion lay entirely in the nerves, and that it progressed centripetally, seven years ago he decided to place a piece of rubber tissue just distal to the ganglion between the severed portions of the second and third branches of the nerves. The success of this operation was as perfect as any which had been obtained with a complete removal of the ganglion, and it was needless to say, infinitely safer and preferable. At this time the patient was still alive and well, and in his large series of cases which he had done on similar lines, he had a number which had passed the three-year limit. He had found it very helpful to tie the external carotid artery just before opening the skull. This he was now in the habit of accomplishing through a vertical incision just in the region of the hair line which he followed in trephining, enlarging the opening with a rongeur as much as might be necessary. This he preferred to the bone flap operation which was so disfiguring.

Dr. George R. Fowler of Brooklyn, in opening the discussion, said that years ago he had tied the external carotid, but that now he preferred to compress both arteries with tapes. It was desirable, he said, scrupulously to avoid pressure on the internal jugular vein.

Dr. George R. Brewer of New York said that eighteen months ago while attempting to remove a gasserian ganglion he had encountered a terrific hemorrhage, which he tried in vain to quell for more than forty minutes. He then decided to section the second and third divisions and interpose the rubber dam. He obtained primary union, and in this, as well as in another done voluntarily a year ago, the result had been all that could be wished for. He believed that a retardation of the arterial supply by means of compression of ligation of the carotids was of very little use, because the hemorrhage was venous and came from a branch of the cavernous sinus.

Dr. Abbe, in closing, said that most cases of trigeminal neuralgia were due distinctly to a neuritis which had its origin in the disorders of teeth or infection of the maxillary antrum. If the operation were undertaken before the disease had hopelessly ruined the ganglion, it was absolutely safe to predict a positive cure by the simple and safe introduction of his rubber barrier.

Single Ulcer of the Urinary Bladder Non-tuberculous and Non-malignant, with Report of Cases.—Dr. George E. Armstrong of Montreal gave the history of a case upon which he had operated under the supposition that it was one of tuberculous ulceration. He found, however, a single perforated ulcer, the walls of the bladder being otherwise absolutely normal. On looking the matter over he found that such lesions of the bladder had been ascribed to infection, to thrombosis, or to syphilis. But he believed there was ground for thinking that his was not

an example of any of these commonly recognized types.

A Case of Enchondroma of the Spinal Column.—Dr. H. R. Wharton of Philadelphia read this paper. He reported a case in which he had removed a large cartilaginous growth from the right side of the lower spine. It was an exceedingly rare condition, three others only having been reported.

AMERICAN GYNECOLOGICAL SOCIETY.

Joseph E. Janvrin, M.D., New York, President.

First Day—Tuesday, May 12.

Address of Welcome.—Dr. I. S. Stone of Washington delivered this address, to which Dr. Janvrin responded.

Discussion: What Shall Be the Treatment in Cases of Pregnancy Complicated by Fibroid Tumor?—Dr. Henry C. Coe of New York read this paper. He stated that the gynecologist who regarded every case of fibroid from a surgical standpoint would naturally take a more serious view of this complication than he who was disposed to be more conservative. Moreover, the wider one's obstetrical experience, other things being equal, the more he would be inclined to assume an expectant attitude, knowing that nature often overcame obstacles which at first sight seemed insuperable except by the aid of the accoucheur. He said that fibroids complicated pregnancy by interference with the normal development of the pregnant uterus; by causing distressing symptoms; or by jeopardizing the life of fœtus or mother. Each case was one by itself, and its treatment varied according to the patient, tumor, experience, and bias of the surgeon. He classified cases of pregnancy complicated by fibroid as: Those in which pregnancy would doubtless go to full term with the prospect of a normal delivery. Those in which the patient had to be kept under constant observation in view of the necessity of possible interference. Those in which there was considerable risk to mother or child, or both, before and during labor. Cases in which surgical intervention was absolutely indicated. Hence the treatment should be entirely expectant; non-surgical, with possible anticipation of the date of normal delivery; surgical, either conservative or radical. Up to the fourth month the uterus should be emptied in the case of large interstitial, or broad-ligament tumors, or when they were situated in the lower uterine segment, or in case of impacted intrapelvic growths. Small tumors should be enucleated per vaginam if possible, though pregnancy would usually be interrupted. Intrauterine polypi, if accessible, should be removed. He believed that the indications for abdominal section for the conservative treatment of fibroid, during the first trimester, were limited. Pedunculated subperitoneal tumors could be easily extirpated without disturbing the uterus. This was entirely justifiable in the case of movable fibroid of considerable size. Impacted growths should be freed under anæsthesia (when there were no adhesions), and kept out of the pelvis until they were kept out of the way by the growing pelvis. Between the fourth and seventh months the conditions were different, since the interests of the fœtus were more important. Location of the tumor, as well as size and variety, were important. Pain and pressure-symptoms furnished indications for treatment. In large interstitial growths the uterus could be emptied, though danger of hemorrhage was greater. Enucleation of Tessier fibroids by the abdominal route, after the middle of pregnancy, admitted of considerable discussion. Impacted tumors, pressing on bladder, ureter, or bowel, might call for radical operation. Twisted pedicle, degeneration of the tumor, peritonitis, etc., might require interference without reference to pregnancy. After the sixth month, a viable fœtus should be obtained, if the mother's life was not actually jeopardized. After the middle of the eighth month, the indications were clear to delay as long as possible, and then to perform an elective section near or at term, or at the beginning of labor, as might seem best. Conservatism should be practised here as in other gynecological operations, but not carried to extremes. The question of marriage and subsequent risks of pregnancy in women with fibroids, should be discussed. The propriety of performing a conservative operation (myomectomy), for the removal of the tumor, should be considered. Under proper limitations this would be quite justifiable.

Myomectomy or Hysterectomy?—Dr. Joseph Taber Johnson of Washington presented this communication. He said that cases of pregnancy complicated by fibroid tumor, were fortunately the rare exception. His own experience was limited to two cases, equally successful, so far as the mother was concerned. In one of these he performed a supravaginal hysterectomy, the uterus containing a five-months' fœtus, as well as a large fibroid tumor. In the other case, the operation was terminated as a myomectomy, the woman being four months pregnant. She was delivered five months later of a live child. Both mother and child did well. The speaker said that his inclinations were upon the side of the conservative operation which had for its object the saving of the child. When the tumor was so situated as to threaten the safe continuance of the pregnancy, and to jeopardize the life of the mother during labor, some kind of operative interference was demanded in the interest of humanity and of good surgery. Formerly supravaginal hysterectomy was the operation of necessity, but with the evolution of a safe and more comprehensive abdominal technique, myomectomy should become more and more the operation of choice. The treatment depended upon the size, variety, and location of the tumor, and the stage of the pregnancy. There were occasional cases with such urgent symptoms as to require supravaginal hysterectomy as a life-saving operation. Every case had to be managed according to the exigencies which arose as pregnancy advanced. As these complicating tumors were not amenable to medical or electrical treatment during pregnancy for obvious reasons surgical relief was necessary in the class of cases in which this remedy was not worse than the disease. As many of the minor methods of treatment could not be used on account of existing complicating conditions, the major operation was imperative. As to whether that should be hysterectomy or myomectomy—would depend upon the case. An interstitial or submucous fibroid complicating pregnancy had to be treated by hysterectomy if any operation was required. In the case of a subperitoneal tumor, especially if it were pediculated, myomectomy was comparatively safe. The speaker cited various cases giving the results of operations in these cases, and concluded by declaring that in cases of pregnancy complicated by fibroid tumors, when any operation was required, and the tumor was so situated as to make it possible, myomectomy should be considered the operation of election.

Pregnancy and Labor Complicated by Myomata.—Dr. George Tucker Harrison of New York read this paper. He said that no general rules could be laid down with reference to treatment. Each case had to be carefully studied in all its circumstances before recourse to operative intervention. It could not be denied that the dangers incident to this complication of pregnancy as a cause of dystocia were formerly vastly overrated. The site of the myoma was a matter of prime importance. Small subperitoneal myomata interfered with conception only under rare circumstances, and did not disturb the course of pregnancy. Large subperitoneal myomata more frequently formed an obstacle to conception by disturbing the normal relations of the adnexa. The existence of a myoma in itself did not furnish an indication for operative intervention; it was only when symptoms were caused by it, which jeopardized life and health, that operative interference was justifiable. If, on account of the severity of symptoms, the continuance of pregnancy was undesirable, it might be necessary to have recourse to enucleation per vaginam. If it was a cervical myoma, supra-

vaginal amputation might be indicated, or myomectomy. During labor, if the tumor was high up, the surgeon should observe masterly inactivity. When the tumor was wedged in the pelvis, cautious attempts at reposition could be made. When the myoma presented an absolute obstacle to the birth of the child, the Cæsarean section was indicated. The speaker cited some interesting cases. The plan of treatment during pregnancy, as a rule, was an expectant one. The majority of cases of women affected with myomata could be expected to pass safely through the perils of childbirth, and the puerperal state, but it was part of wisdom to be prepared for any emergency.

Dr. E. Reynolds of Boston emphasized the fact that no surgeon should operate on a fibroid in pregnancy when this could be avoided, on account of the vessels at term.

Dr. J. D. Emmet of New York said that some myomata had to be removed, while others did not interfere with the course of pregnancy

Dr. William R. Pryor of New York believed in great conservatism in cases in which the fibroid uterus was pregnant. Fibromata were particularly soft, accommodating themselves to the situation. He illustrated his method of operation and said that the important part of the technique was to avoid the cervix and to inflict all trauma on the fibroid only. He advocated the administration of mammary extract in the puerperium, beginning the treatment as soon as the patient could take general diet, and continuing it for six weeks.

Dr. Reuben Peterson of Ann Arbor declared that these tumors could be removed with safety from a patient five or six months pregnant. He described a case in which he operated. The patient was five months pregnant, but the tumor was not softened.

Dr. Engelman believed in the administration of mammary extract, since it favored the process that pregnancy tended to. He had seen the disappearance of softening fibromata.

Dr. Freeman also related cases in which the tumors became gradually smaller. These tumors generally cared for themselves. Retrogressive changes often took place.

Dr. James Clifton Edgar of New York agreed in this statement that these tumors often took care of themselves. Out of sixteen or seventeen thousand cases of which he had the oversight, he remembered only about half a dozen in which fibromata or myomata caused dystocia.

Dr. George Tucker Harrison of New York called attention to the frequency of myomata in the colored race. He said that we might expect a retrograde metamorphosis in these tumors in the puerperium.

Combined Bisection of Tumors and Uterus with Enucleation of the Former in Abdominal Hysterectomy for Large Fibroid Tumors.—Dr. George H. Noble of Atlanta reported a procedure which greatly expedited the removal of large fibroid tumors filling the pelvic cavity and extending laterally above the pelvis to the walls of the abdomen. This method also gave the operation at all times excellent control over the blood supply of the part. The operation had as its underlying principle the bisection of tumor and uterus, together with subsequent partial enucleation of each half of the tumor separately. He described a special retainer which he used to keep the intestines and omentum well up out of the way. In case of large fibroids in the body of the uterus the tumor was bisected, the uterus was bisected, and the bisected tumor was enucleated. The halves were rotated, in the process of enucleation, on their outer (upper) cut margins, the inner (lower) margin describing a semicircle in transit. The two halves of the tumor then lay on opposite sides of the patient's body, the flat cut surface looking downward and the convex enucleated surface looking upward. Both sections were connected by long pedicles to the uterine stump. The advantages of combined bisection of the tumor and uterus with partial enucleation were: saving in time, decreased loss of blood, increased working space, easy manipulation and safety against injury to the uterus and uterine arteries. The advantage of time saving was apparent, since prolonged operations contributed largely to shock. The speaker exhibited some fine plates and a very ingenious diagram.

Dr. Pryor said that by bisection, both mobility and symmetry, could be established. He called attention to the fact that growths caused distortion and fixity.

Dr. Stone said that the surgeon should always be on the lookout for abnormal division of arteries, and consequent danger of hemorrhage.

Relation and Co-relation of Gynecological and Nervous Affections.—Dr. Chauncey D. Palmer of Cincinnati presented this paper. He said that the intimate history between the nervous system and other parts of the body in disease was only in accordance with the general law of morbid action. The most varied phenomena, apparently trifling, yet serious at times, might result from the same pathological entity. The morbid changes to which reference implied were: hysteria, neurasthenia, neuralgia, chorea, epilepsy, catalepsy, hystero-epilepsy, certain paralyses, migraine, convulsions of certain kind, including tetanus; also mental aberrations, and vasomotor changes. While many hysterical women had no anomaly of the sexual organs, a certain proportion to a certain degree had some imperfection in the development of their sexual apparatus, especially the uterus. Hence the justifiability of an oophorectomy in some such cases. Should the sexual organs be diseased in hysterical women, we could not say that the hysteria was secondary. Even then psychical causes were at work, more potent than the local disease. Errors in diet, in general hygiene, in lack of rest, etc., in girlhood, lead to physical anomalies, and give rise to abnormal mobilities of the nervous system. The functions of ovulation and menstruation played then more than their oridnary rôle in the inauguration of nervous phenomena. Insanity had been promptly relieved by ninety-seven gynecological operations; and it had immediately followed them. Such sequelæ then noticed were probably more common than after other operations. Probably the ovaries were more frequently the *fons et origo morbi*. The sexual organs played a small part in the production of mental disorders. But 25 per cent. of insane women had any gynecological disease. No amount of pelvic or general physical disease could cause a psychosis, unless conditions favorable thereto were to be detected in the brain or in the nervous system.

Dr. J. D. Emmet said that much hysteria was associated with laceration of the cervix and disorders of the pelvic organs.

Dr. Johnstone said that the blood condition should be considered and the toxæmia arising from its impure condition. Absorption from both the genital and intestinal tract should be prevented.

Bence Jones' Albumosuria, with Peculiar Nervous Phenomena.—L. Napoleon, Boston, reports a case of albumosuria. The patient suffered severely from neuralgia. There has often been a feeling of "giving away" of the left leg, and the bones of the left pelvis while walking or going upstairs. Neuralgic pains in the left shoulder, which radiated to the left hand were most annoying. At times there was numbness, and a feeling of "pins and needles," in the left arm and hand. There have been cramp-like pains in the left thigh, leg, and foot. The left knee-jerk and the plantar reflex were decidedly increased, and ankle clonus was marked. In the blood examination, the erythrocytes were always above 4,000,000. The mononuclear leucocytes amounted to 56.75 per cent., and the polymorphonuclears to 39 per cent. Hæmoglobin was very low, being at one time 39 per cent.—*The American Journal of the American Sciences*, April, 1903.

AMERICAN PEDIATRIC SOCIETY.

First Day.—Tuesday, May 12.

President's Address.—Dr. J. P. Croger Griffith of Philadelphia, as president of the society, gave expression of his appreciation of the honor conferred upon him and said that he had not chosen to present any medical subject since the session was so curtailed for time. He said that while the knowledge of having helped so many little patients and the consciousness of work well done was in itself a source of gratification to the physician, any work which made treatment better was more far reaching. This society had accomplished much to advance pediatrics. Since its organization fifteen years ago, three hundred and ninety-two articles had been presented to the society, many of which were of international as well as of national value, individual and collective work on the disorders of the digestive tract, diphtheria and infantile scurvy had been of especial value. It was estimated that one thousand five hundred and thirty-five articles had been contributed to medical literature during the past fifteen years by members of the society outside of the pediatric records. Thirty works had been added to text-book literature, several members had contributed sections to the composite text-books and two pediatric journals had been established Dr. Griffith said that there was a tendency to become too practical, financial interests and other things should not interfere with scientific research, the members were urged to devote more time to scientific investigations, both for the maintenance of the reputation of the society and for the advancement of this branch of medicine.

Synopsis on Some of the Renal Lesions in Infancy.—Dr. C. F. Martin and Dr. F. M. Fry of Montreal had prepared this paper which was based on a study of one hundred cases of nephritis in infants under three years of age. Sixty-five were artificially fed, thirty-five were breast fed, the specific gravity of the urine varied, the highest was 1.028—the lowest 1.001—the average was 1.006 Ascites was present in nineteen cases, albumin was present in variable amounts, only two having albumin without casts. There was an excess of uric acid in thirty-six cases.

Report of a Case of Chronic Nephritis in a Four-year-old Boy Having Only One Kidney.—Dr. A. C. Cotton of Chicago read this paper. The child had been a normal healthy baby, had had measles, and six months later had pneumonia lasting five weeks, followed by a relapse lasting six weeks. He never fully recovered from this last sickness, but began to develop œdema of the ankles and around the eyes. Urination was frequent. Diuretics, the hot pack and saline enemeta were given from time to time, the patient grew slowly worse with intervals of apparent improvement and died of uræmic intoxication. During the course of the disease urine analysis showed a progressive diminution in the amount of urea, the amount of total solids closely followed that of urea. Albumin was constantly present in variable amounts, granular hyaline and occasional waxy casts had been found. On autopsy clear serous fluid was found in the pleural, pericardial, and peritoneal cavities. The right kidney weight sixty-five grams, the capsule was stripped easily but left an irregular surface, the cortex was pale, markings indistinct. The left kidney was rudimentary, consisting of a small triangular body with base uppermost, one centimeter long and one and a half centimeters broad at the base. An artery and a vein could be traced from this body to the aorta. The right ureter was normal, the left terminated in the rudimentary kidney and contained no demonstrable lumen.

A Case of Edebohls' Operation.—Dr. T. M. Rotch of Boston read this paper, in which he reported the case of a child nine years old who had a severe nephritis. Edebohls' operation was done and the child died two weeks later. Dr. Rotch said that the subject of renal disease was in its infancy, and that as yet there was no proper nomenclature to designate the various pathological conditions. The marked beneficial results that have been attributed to this operation had attracted much attention, but many of these may have been functional cases and would have recovered without operation. As yet the limitations of the operation were unknown.

Dr. George M. Edebohls, when asked to discuss this case, said that at present he had nothing to add to his article published in the Medical Record, March 28, 1903. He stated that it would require four or five years before positive results could be pronounced.

Dr. B. K. Rachford of Cincinnati said that most cases of nephritis in children tended to complete recovery, while in adults the tendency was for the process to become chronic, and for this reason the value of the operation should be determined by the results obtained in adults. If operation was resorted to in cases of less that six months' standing in children, it was impossible to determine whether recovery or death was due to the operation or the natural cause of the nephritis.

Dr. Rotch said that chronic nephritis existed in children as well as in adults, and some die of it, but not frequently. Further study would be necessary for a discrimination of cases favorable or non-favorable for operation, but the nephritis of childhood and that of adults formed two distinct classes each of which must be studied separately.

Dr. C. G. Jennings of Detroit reported a case of chronic renal disease in a child, with persistent severe pain and tenderness over the left kidney. The urinary findings were those of a chronic interstitial nephritis. At operation no microscopic pathological changes were seen. The capsule was split and stripped from the kidney. The child made a complete recovery in two months.

Dr. Cotton said that chronic nephritis in children was not as rare as was formerly thought; he had had four bad cases come under his notice during the past year.

Exhibition of a Case of Club-feet Operated on by Professor Lorenz.—Dr. Samuel S. Adams of Washington, D. C., presented this case, which had previously been subjected to five operations of tenotomy. The deformity was extreme; the child standing on the outer side of the small toes. Professor Lorenz corrected the deformity by pressure with his hands, occupying twenty minutes to each foot. The feet were put in plaster casts for three months before the child was allowed to walk without support, the casts were to be reapplied for several months longer.

A Case of Abscess of the Lung—Dr. Adams, in presenting a second case, described a child two years old who gave physical signs of fluid in the left lower chest and of the consolidation in the left upper chest. The patient had an irregular febrile temperature. About a drachm of pus and bloody serum was obtained from the left upper chest with an aspirating needle. A diagnosis of empyæma was made, but at operation no pus was found in the pleural cavity. The child died twenty-four hours after operation. On autopsy the left lung was found adherent from base to apex, and contained several small abscesses in the upper lobe. The right lung was normal. The abscess was due to a streptococcus infection.

Dr. Colton said, in discussion, that cases were not rare in which pus was found by the aspirating needle, but not found at operation, and *vice versa*, the pus being walled off by the adhesions of a fissural pleurisy.

Brutalities in the Convict Camps.—It is reported from Atlanta, Ga., that revelations made to the Ware County Grand Jury in regard to horrors of the Georgia convict camps have reached Governor Terrell, and promise to cause such a sensation that the rease system may be overturned.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

GENERAL SESSION.

SECOND DAY—WEDNESDAY, MAY 13.

The Medical and Surgical Aspects of the Diseases of the Gall-bladder and Bile Ducts.—This was the special subject for discussion.

The Medical Diagnosis of Affections of the Gall-bladder and Bile Ducts.—Dr. JOHN H. MUSSER of Philadelphia presented this paper. He said that of the primary affections there were, inflammations (catarrhal and infectious), morbid growths and parasite invasions, such as with the echinococcus and the round worm. The secondary conditions were inflammations of the gall-bladder, cholelithiasis and obstruction and enlargement of the gall-bladder. He would especially plead for the early recognition of these primary states, for if this were done the secondary conditions would, in time, become things of the past. He was disposed to predict that fifty years hence there would be little seen of these secondary conditions. The blood was the best test of the degree of jaundice present in a given case. The recognition of suppurative cholangitis was based upon the probabilities of infection somewhere in the biliary passages—a preceding history of gallstones or of parasite invasion. The fever was of a peculiar character, being usually either remittent or intermittent. The occurrence of tenderness about the twelfth dorsal vertebra was an aid in the diagnosis of the suppurative diseases of the biliary passages. He had found leucocytosis in all of the cases he had seen. The serum reaction was of value in enabling one to determine the possible cause of such affection. He had seen six cases of cholecystitis occurring in typhoid fever during the past few months. None of these had led to the suspicion of perforation of the bowel having occurred. In making the diagnosis one must distinguish between congestion of the liver, multiple abscess of the liver, pyelophlebitis, subdiaphragmatic abscess, diaphragmatic pleurisy, pneumonia, pancreatic disease, perforation of the bowel and intestinal obstruction.

Surgical Differential Diagnosis of Diseases of the Gall-bladder and Bile Ducts.—Dr. GEORGE E. BREWER of New York City presented this paper. He said that the diseases ordinarily encountered in diseases of the gall-bladder and bile ducts were, calculous disease, inflammatory disease, and new growths. One or more stones in a patent gall-bladder usually produced no symptoms, and the only physical sign was a tumor of the gall-bladder. The existence of a number of gallstones had been occasionally detected by the presence of a peculiar bruit, and occasionally a stone could be distinctly palpated. If a calculus were temporarily impacted in the neck of the gall-bladder, or the cystic duct, pain would be produced. It varied in intensity from a slight feeling of discomfort to a colic, the intensity of which was only equaled by the pain of the second stage of labor. The attack often ceased suddenly by vomiting, which, by relaxing the spasm, allowed the calculus to fall back into the bladder. If the stone became permanently impacted, or the duct became permanently obstructed in any other manner, a gradual increase in the size of the gall-bladder occurred by an accumulation of fluid within its cavity. In the absence of infection this fluid was sterile and gave rise to no discomfort except that resulting from pressure. A tumor of this character developed slowly, and was situated immediately behind the abdominal wall at the free border of the ribs; it developed downward and somewhat toward the median line, and moved laterally with a pendulum motion. The gall-bladder had been occasionally found near the median line, and congenital absence had been once observed by himself. The passage of a gallstone through the cystic duct gave rise to painful sensations. It was formerly held that the transit of such a stone was practically the sole cause of biliary colic. Kehr, and a number of others, held that the pain in gall-bladder disease was practically always the expression of an inflammatory process. All were agreed that acute paroxysmal pain in the upper abdomen was the most constant and characteristic symptom of cholelithiasis. The diagnosis of stone in the hepatic duct was often very difficult. The diagnosis of stone in the common duct was less obscure, the chief symptoms being jaundice, pain, and fever. Acute temporary common duct obstruction from stone produced a rapidly developing jaundice. Pain in common-duct disease strongly pointed to stone. If fever were present, it was apt to be intermittent and associated with chills. When present with jaundice and colic, it was almost pathognomonic of stone in the common duct. This fever was most probably of septic origin. Inflammation of the gall-bladder was present in the large majority of the cases applying to the surgeon for relief. Cholelithiasis was rarely found in young subjects, only about 2 per cent. of the cases occurring in persons under twenty years of age. Half of all the cases of common-duct obstruction were due to stone. The temperature chart in biliary affections was characterized by angularity rather than by curves. Jaundice was absent in from 80 to 90 per cent. of all ccases. Special attention was directed to the presence normally of three lymph nodes, and to the fact that enlargement of these nodes might readily produce a typically progressive jaundice resembling that seen in carcinoma.

The Etiology and Pathology of Gallstones.—Dr. C. A. HERTER of New York City read this paper. He said that the chief elements of a gallstone were cholesterin, bilirubin, and calcium. Very little was known of the origin of cholesterin except that hepatic bile contained a small proportion of cholesterin, and that this was derived, in all probability, either from the blood or from the hepatic cells themselves, and that this cholesterin, entering the gall-bladder, became increased in quantity. It had generally been supposed that this was due to an inspissation of the contents of the gall-bladder, but it was far more likely that the increase in the cholesterin found in the cystic bile was due to the actual production of cholest rin by the epithelial cells in the gall-bladder. In health this increase was very slight, but in disease this increase might become so great as to assume a pathological significance. He had conducted some experiments to see if it were possible to increase the cholesterin by the production of an artificial cholecystitis. In twenty observations upon normal dogs it was found that the cholesterin of the bile gave an average of 0.12. In twelve dogs in whom mercuric chloride was injected into the gall-bladder, it was found that the average amount of cholesterin was 0.298. When strong phenol was used, the average was 0.334, but, when diphtheria antitoxin was injected the quantity of cholesterin did not differ materially from the normal. It was concluded from these observations that the introduction of concentrated irritants into the gall-bladder was quickly followed by a material increase in the cholesterin in a very large proportion of the cases. There was but little doubt that this cholesterin was derived from the epithelial cells of the gall-bladder. In human cystic bile obtained from forty autopsies it was found that the average percentage of cholesterin was 0.13, not very much in excess of the normal. The average from six cases of acute miliary tuberculosis gave 0.167 per cent., and in eight cases of acute lobar pneumonia it was 0.248. He was inclined to believe from the last item that there was a marked and very regular increase of cholesterin in the cystic bile, occurring in the course of acute lobar pneumonia. He was inclined to think that the explanation was to be sought in an inflammatory and infectious condition of the bile itself. With regard to the origin of the calcium, the speaker said that normally the calcium of the cystic bile was about that of the normal blood, or a little higher. It was probable that the calcium was derived largely from the blood or from mucus and epithelial cells. It was

found that the same irritants which increased the cholesterin very markedly did not augment the calcium in a corresponding degree. It was probable that any condition of cholecystitis was liable to be attended by an increase in the amount of calcium in the bile, and this was significant, because if it reached a certain point the calium was liable to combine with bilirubin and precipitate a compound known as bilirubin calcium, a perfectly definite chemical compound which formed the nucleus of a great many stones. In 1890 Dr. Welch had found in the centers of many gallstones the presence of the streptococcus pyogenes or the colon bacillus. Since that time it had been found by other observers that, in a very large proportion of cases, probably one-half, there was a bacterial nidus for gallstones. The artificial production of gallstones had been first accomplished in 1897. It was found that it made very little difference what organism was employed provided it was a pathogenic organism of only moderate virulence. It was also found necessary to retain the organisms in the gall-bladder. The natural flow of the bile had more to do in protecting against infection than had any inherent antiseptic properties it might possess. Stagnation of the bile was, therefore, an essential factor. With regard to the constitutional origin of gallstones, the speaker said that he had recently made some experiments upon dogs. These animals had been kept upon a diet consisting almost entirely of fat, and at the end of three months minute masses of bilirubin calcium were found in the gall-bladder, and in one instance there was a distinct concretion. He had never before met with such a concretion in over 100 gall-bladders examined by him in other dogs. In conclusion, he emphasized the fact that by means of irritants it was possible to increase largely the quantity of cholesterin without the presence of an infection. He believed there was substantial evidence to indicate that constitutional conditions might play a not unimportant part in determining the production of cholelithiasis.

Diseases of the Gall-bladder and Bile Ducts with Special Reference to Diseases of the Stomach and Intestines.—Professor Ewald of Berlin, Germany, presented a communication on this subject. He said that in most cases cholecystitis was the result of catarrhal affections associated with bacterial invasion. Colic implied contraction, and occurred when the stone was movable. Renal colic could be differentiated from gallstone colic without much difficulty, and the pain associated with hernia of the linea alba was also easy of recognition if such conditions were borne in mind. In most cases of nervous gastralgia there were hyperacidity and hyperchlorhydria. The latter could occur reflexly from the intestine, as, for example, by a tapeworm. With regard to tumors of the gall-bladder the speaker said that a gall-bladder filled with bile never became as large as a hydrops. Aspiration of the gall-bladder was a dangerous procedure, and, moreover, was not necessary because the character of the tumor could be much better determined by an abdominal incision. Carcinoma of the gall-bladder was complicated in 95 per cent of the cases by cholelithiasis. He had found the internal treatment of cholelithiasis very unsatisfactory. He looked upon the surgical treatment of this disease as being in very much the same position as that of appendicitis. Not all cases of appendicitis were necessarily treated surgically, and the same was true of of cholelithiasis. At the operation stones might be left behind, or it might be impossible to remove all of them, and even after operation one could not be sure that there would not be a recurrence.

A Study of 534 Operations upon the Gall-bladder and Bile Passages.—Dr. William J. Mayo of Rochester, Minn., presented this paper. He said that the gall-bladder had been slow to receive from the medical public the attention which it deserved. This was partly because the subjects of this disorder were apt to be elderly and poor subjects for surgical operations, and the disease, as a rule, did not declare itself with tragic suddenness. In St. Mary's Hospital, in the year 1902, there were 345 operations upon the appendix, 143 on the gall bladder, 98 on the ovaries and tubes, and 77 on the stomach. The operations on the gall-bladder representing the basis of this paper were done on 518 patients with 19 deaths, or a mortality of 3.5 per cent There were 510 operations for gallstone disease with a mortality of 3 per cent. That the large majority of adults with gallstones never suffered was true, yet if these stones once became active the chances of securing relief was not good, even though there might be long intervals of freedom from pain. A gall-bladder containing stones was always infected, and when the organ once became restless a chance for reconciliation was improbable. In some of the cases marked contraction of the gall-bladder or adhesions indicated that at one time the disease had been active. The mortality in the uncomplicated cases operated upon was low, and the operation itself was of the simplest character. Cholecystostomy not only effectually cured the condition, but by permanently lifting the fundus gravity drainage ensued in the future. However, the safety with which cholecystectomy could be performed at the present time made it probable that this would become the operation of the future. If the stones were impacted the colic would be replaced by a constant distress, which was less acute but more continuous. In such cases, as a rule, the stones could be dislodged and brought out through the gall-bladder by an ordinary cholecystostomy. In 183 operations for impacted stones, there were six deaths, or a mortality of 3.25 per cent. In ninety-eight cholecystectomies the mortality was a little over 3 per cent. Kehr, Robson, and others of large experience in gallstone surgery united in declaring that they had not known of recurrence of gallstones, and this had been his own experience, although he had known the opening to cicatrize before all of the stones had been discharged. Not infrequently stones passed out through the common duct and into the bowel, but they had never met with a case of this kind in which others had not been left behind. The surgery of the common duct had become a fairly safe field To the late Dr. Davis of Alabama we owed the most important contribution to this subject. He called attention to the necessity for freely draining the bile to the surface, and to the fact that suture of the duct was unnecessary and was occasionally harmful. If the cystic duct were open so that the bile could flow freely to the surface, suture of the gall-bladder might be harmful. The incision through the abdominal wall, modified by Robson, rendered the removal of the common-duct stones easy. In a few cases incision of the duodenum and direct extraction might be necessary. Professor Kehr had explained the usefulness of hepatic drainage, and had shown us how to cure some cases which had heretofore been considered hopeless. In his series of operations there were fifty-eight for stones of the common duct, and of this number three died. The relative proportion of common-duct stones was 11 per cent. of the whole, but even this was too high, for gallstones should be diagnosed in most cases before common-duct symptoms clinched the diagnosis and forced operation upon the patient. Cases of chronic cholecystitis were very interesting because of the danger of overlooking the condition at operation, owing to the absence of gallstones, although the gall-bladder would show evidence of disease. Sixteen of their cases came to a second operation. The average stay in the hospital was about three weeks. The sutures closing the abdominal incision were left in place for two weeks, thus allowing the patient to get up early, a matter of no small importance in old people. If there was a tendency to hemorrhage the patient was given a preparatory course of chloride of calcium. In severe cases bile drainage to the surface was essential, and for this purpose the cystic duct, if obstructed, supplied an easy escape. Malignant disease of the gall-bladder and bile ducts was met with twenty-

four times, or 4 per cent. of the total number of cases. In five cases the gall-bladder was removed for cancer. Three of the patients were still alive, one nearly two years after the operation, but with a recurrence. The speaker was of the opinion that gallstones were the chief and primary factor in the production of malignant disease. One case in twenty-five of this series of operative cases had malignant disease. It was probable that in the future many cases of cancer would be removed in the early stage, with a permanent cure.

Surgical Treatment of Obstruction of the Common Bile Duct by Stone or Tumor.—Prof. Hans Kehr of Halberstadt, Germany, was the author of this paper. After reading the introduction in the German language, a translation of the paper was read by the Secretary of the Congress. The author stated that acute obstruction by calculus demanded special discussion because it was not uncommon, and in all but a very small number of cases, laid the foundation for obstruction of the duct. He was of theopinion that the pressure of the bile dammed back by inflammatory processes, was the chief factor in forcing stones through the duct. Not infrequently one had to deal with several stones. At the time of the colic one could not determine whether the stones were large or small, whether they remained in the common duct or passed there. The expectant treatment was the only rational one in the presence of acute obstruction of the common bile duct. It was the duty of the physician by means of rest, hot applications, and the administration of sodium salicylate and other drugs to assist nature in bringing about the natural elimination of the stone. The stools should be carefully examined for the presence of calculi. If stones were found; if icterus entirely disappeared, and if absolutely no tenderness remained in the hepatic region, there was, of course, no ground for an operation. There were exceptional cases of acute obstruction of the common bile duct in which the icterus did not subside, and in which fever and rigors developed and the appetite diminished. Even in such cases sudden improvement might occur, or, on the other hand, through cholæmic hemorrhage, a fatal termination might be precipitated. In such cases the question of operation should be seriously considered. However, this particular indication presented itself very rarely, as in 800 cases he had found it necessary to operate in the presence of acute obstruction in only four instances. Where there were frequent attacks of gallstone colic, even though stones were constantly passed after such attacks, experience showed that the gall-bladder was usually filled with stones, and hence surgical treatment was in order. In these cases the nature of the colic, the accompanying fever, the addiction to morphine, and the condition of the patient in the intervals would help to settle the question. On the other hand, in chronic obstruction of the common bile duct the indication for operation was very frequent. Cases of common-duct obstruction without icterus, colic, or fever were met with, although stones were passed. Again, in some seemingly desperate cases a spontaneous cure might occur, but it was not advisable to wait for the natural process of cure, not only because it was very rare that this occurred, but because the delay incident to this was attended by dangers greater than that of the operation. In the last few years he had lost scarcely 3 per cent. of uncomplicated common-duct obstruction cases, yet an operative mortality of 20 per cent. need not be considered excessive in a class of cases in which 80 per cent. would sooner or later succumb to the disease. No one could make him believe that a course of treatment at Carlsbad accomplished more than the conversion of the disease into the latent form. A long course of drinking Sprudel Wasser was often more dangerous than opening the belly. In most of his operative cases it had been necessary to incise the common duct for the removal of the stone. The operation of cholecystenterostomy he looked upon as one of necessity only, and he had never performed it. It was his rule now to leave the duct open for drainage. He strongly recommended drainage of the hepatic duct, and freely conceded that this was a procedure of American origin.

Dr. Frank Billings of Chicago opened the general discussion. He said that the most common symptom, even of cystic gallstones, was pain, yet in the early stages this might not amount to more than tenderness. Frequently on making pressure over the region of the gall-bladder there was a pain or tenderness reflected toward the epigastrium. Other conditions would cause pain in this region. He had recently seen two patients who had been operated upon for gallstones when there were no such stones present, and the pain was really a symptom of the gastric crises of locomotor ataxia. When the diagnosis of gallstones had once been made he felt sure that it was no longer a medical disease.

Dr. George Dock of Michigan said that most of the conditions simulating gallstones could be separated by an exhaustive examination. There would be a loss of valuable time, and perhaps of life by temporizing with cases of stomach disease because of confounding them with cholelithiasis.

Dr. Henry Sewall discussed the physiology of the flow of bile. He said that germs once in the common duct must find ready access to the gall-bladder. The principal use of the gall-bladder probably was to serve as a flushing tank for the common and cystic ducts, and accordingly it might be suspected that extirpation of the gall-bladder might predispose to gallstones. Duodenal catarrh extending into the gall duct must at least lead to stagnation of bile. The amount of cholesterin formed must depend largely upon the general health.

Dr. E. G. Janeway of New York City said that when a question arose as to a permanent condition, such as carcinoma of the pancreas or a tumor there and a stone, which was not completely obstructive, the character of the food taken by the patient should be under the control of the physician. He was led to mention this because he had known of a recent case in which it had been assumed from the darkening of the stools that there was flow of bile, whereas further inquiry showed that this discoloration was due to the patient's having eaten very freely of spinach.

Mr. B. S. A. Moynihan of Leeds, England, said that formerly operations done there upon the common duct had been attended by a very high mortality. This had, however, been greatly reduced, a fact which was largely attributed to the use of a vertical incision continued upward on to the costal margin. About one-third of the liver with the gall-bladder was pulled out of the wound; thus making the common duct straight with the cystic duct and on a level with the skin. This detail of technique had given them, in England, very great satisfaction, and had markedly shortened the operation. They were doing cholecystectomy at present very much more frequently than formerly in preference to cholecystostomy.

The evening of the last day was given up to a "smoker" at the New Willard Hotel, at which Dr. E. A. Locke of Boston, Mass., gave a lantern demonstration of twenty-one cases of Paget's disease (osteitis deformans), and Dr. Richard C. Cabot of Boston, Mass., gave a demonstration of the ring bodies in the blood of anæmic patients.

Estimation of Putrefactive Products in the Urine and Fæces by the Means of Ehrlich's Aldehyde Reaction.—R. Baumstark utilizing the method above described has endeavored to estimate the amounts of indican in the urine and indol in the fæces under both normal and pathological conditions. Since the amount of these substances present under normal conditions is subject to wide variation, it is difficult to apply the results obtained in pathological work with any amount of accuracy. In general, however, it may be said that an increase was found in those conditions which showed marked intestinal fermentation. The diseases thus studied were: chronic constipation, diarrhœa, hyperchlorydia, peritonitis, anæmia, and chlorosis.—*Munchener medicinische Wochenschrift*, April 28, 1903.

FOURTEENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Madrid, April 23-30, 1903.

Section in Surgery.

Surgery of the Posterior Mediastinum.—Dr. J L. Faure of Paris said that the upper portion of the posterior mediastinum was at the present day almost the only inaccessible region of the body, the only practical operation in this part being the simple evacuation of an abscess. It was usually taught that the posterior mediastinum was to be reached by resection of the middle ribs followed by stripping off of the pleura, but this was very unsatisfactory, and, moreover, gave access only to the medium part of the mediastinum. The author's plan was to resect the upper ribs, especially the first, as well as the lower. This permitted a wide opening into the entire extent of the posterior mediastinum, the shoulder falling outward and the apex of the lung dropping away from the spinal column. That this was a feasible procedure was shown by the fact that Dr. Faure had been enabled by it on two occasionsto exsect some twelve centimeters of the thoracic portion of the œsophagus which had been invaded by neoplasms, the operation being attended by no unusual difficulties. The author advised, when practicable to make the operation to the right side of the spine, for on the left side the arch of the aorta would be in the way, and furthermore, in the upper part, the thoracic duct would be in danger of being wounded. On the right side, on the other hand, the cross of the azygos offered the only obstacle, and that could easily be divided between two ligatures.

Radical Cure of Femoral Hernia.—Dr. Otto V. Lassen of Randers, Denmark, said that a simple cicatrix yielded readily to continuous pressure, while muscular tissue firmly united, or a strong aponeurotic tissue like Poupart's ligament, or the linea alba furnished a strong defense against the pressure of the abdominal contents. The methods formerly employed of dissecting up a muscular or aponeurotic layer and fixing it to the crural canal were not very satisfactory, for the nerve might be involved, or the muscle might degenerate and so weaken the defense. The author's method was, after treating the sac in the ordinary way, to clean a part of the pectineus aponeurosis and raise from it a strip about 2 cm. long and 1 cm. wide. Then a curved needle, armed with not too fine catgut, was passed between several of the exposed muscular bundles, and this muscular mass was raised and attached by five or six sutures to Poupart's ligament, at the point where it forms the anterior wall of the canal, and to the falciform fold, so as to close the opening completely, nothing but muscular tissue being seen at the bottom of the wound. The muscular bundles were thus merely raised from their bed and no nerve connections were severed. This method was applicable to all varieties and sizes of femoral hernias. Dr. Lassen had performed this operation forty-five times. Of these forty-five cases he excluded fourteen, dating from less than two years, and, therefore, presumably not yet safe from relapse. Of the remaining thirty-one cases, dating back from two to six years, he had been able to follow up twenty-one. He had examined those patients very recently and had found a relapse in one only, an old woman suffering from chronic bronchitis causing an incessant cough.

Esthetic Treatment of Hernia.—Dr. H. Morestin of Paris presented a communication with this title, in which he contended that it was often possible to conceal the cicatrix following operation for inguinal or femoral hernia by making the incision, whether transverse or vertical, in the hairy regions. Complicated and difficult procedures for the radical cure of inguinal hernia were hardly practicable, though a short incision made at a distance from the field of operation, but the suppression of the hernial sac and folding of the aponeurosis of the obliquus externus will easily be affected in this way.

Surgical Treatment of Hour-glass Contraction of the Stomach.—Dr. Juan Bravo y Coronado of Madrid reported a case of this description, from a study of which and of other cases reported by Eiselsberg, Hartmann, Roux, and others, he felt justified in formulating the following conclusions: (1) Surgical intervention is necessary for the relief of hour-glass contraction of the stomach, (2) The particular operation demanded may vary with the underlying cause of the contraction. (3) The usual operations are (*a*) gastroplasty, (*b*) gastrogastrostomy, (*c*) circular resection, (*d*) gastroenterostomy. (4) The last-named operation may be regarded as the one of election by reason of its simplicity and its general application, for it removes most of the symptoms usually produced by an hour-glass stomach, and at the same time relieves those caused by gastric ulcer when this coexists. (5) When a pyloric stricture exists at the same time with an hour-glass contraction the indication for gastroenterostomy is absolute, none of the other operations mentioned being admissible. (6) A study of all cases to date shows that the results of gastroenterostomy are superior to those of all the other operative methods, especially to those of gastroplasty.

Plugging Bone Cavities.—Dr. M. Silbermark of Vienna read a communication on the method of Mosetig-Moorhof for treating bone disease—caries and osteomyelitis—by filling as a dentist fills carious teeth. The operator removes all the dead bone and a portion of healthy bone surrounding the disease focus. The cavity so formed is thoroughly dried by hot compressed air and then carefully and completely filled by a plug.

Multiple Hydatid Cysts of the Abdominal Cavity.—Dr. Apostolo N. Psaltoff of Smyrna reported a case of this nature in which he performed splenectomy, partial hepatectomy, and ablation of a very large hydatid of the mesentery, the whole operation being completed in one séance. The patient made an excellent recovery.

A Rapid Sterilizer and Water Heater.—Dr. Ramón Martín Gil of Malaga described an apparatus for the rapid heating of water in large quantities, two quarts of sterilized water at a temperature of 105° C being produced every fifteen or eighteen seconds. The apparatus could be used as a steam sterilizer for clothes and bandages or as a sterilizer of instruments by hot water at varying pressure, according to the temperature. The apparatus could be employed for domestic purposes as well as in the operating room.

Treatment of External Tuberculosis by Heat.—Dr. Spiro Clado of [Paris] presented a communication on this subject. He recalled a memoir which he had published in collaboration with Verneuil in 1891, since which time he had treated many cases with results which confirmed the conclusions in the former paper regarding the efficacy of the method. In some cases, when the tuberculous focus was superficial,the treatment by heat was curative by itself, in other cases when the diseased area was less accessible the method offered a valuable adjunct to other and more usual measures. For example, in tuberculosis of the skin, in certain cases of osseous and articular tuberculosis, in accessible tendinous cysts, and in tuberculous laryngitis, the author had obtained many perfect cases. In other cases in which the diseased foci were deeper, heat applied before and after operative procedures had rendered signal service.

Post-operative Mortality.—Dr. José Ribera y Sans of Madrid said that deaths following operations might be arranged under five groups, as follows: (1) Death due directly to the operation. (2) Death due to some complication, so-called traumatic complication, either infective or non-infective. (3) Death resulting from some complication in the part of the organ operated upon, such as loss of cerebrospinal fluid in operations on the head, pneumothorax in operations on the chest, or intestinal occlusion following abdominal operations. (4) Death due to disease of some organ other than that ope-

rated upon or to a bad general condition. (5) Death due to some intercurrent disease unconnected with the operation itself. While death in the fifth class of cases might be called unavoidable, this was not the case in the first four groups, and study of them was therefore necessary.

In many instances, for example, death was directly attributable to the fact that the operation was deferred too late, as in hernia, when delay had permitted the formation of intestinal occlusions or adhesions leading to strangulation. Again death due to the coexistence of disease in other organs might be averted by a more exact diagnosis following a careful examination of the patient; in such cases treatment should be directed to the affected organ before operative intervention was had.

Treatment of Cutaneous Tuberculosis.—Dr. H. Morestin of Paris said that the ordinary treatment of tuberculosis of the skin, of whatever form, should be extirpation, followed by an autoplastic operation. The Italian method of autoplasty was especially indicated after operations on the upper extremity, the Indian method after those on the cheek, a sliding graft and fixation after those on the chest or abdomen, and ordinary grafting in other cases. The technique of the operation for removal of the tuberculous lesions necessarily varied according to the nature and seat of the disease, and the author related several cases in illustration of the methods employed. In all cases, however, surgical treatment of cutaneous tuberculosis was the method of election.

Spinal Cocainization.—Dr. M. da Costa Alemão of Coimbra, Portugal, related a number of observations on this method of inducing surgical anæsthesia. His results obtained after injections of ordinary solutions of cocaine having been very unsatisfactory, he resorted to solutions in cerebrospinal fluid as originally proposed by Guinard. This consisted in making a rather strong solution of cocaine hydrochlorate (each drop containing 5 milligrams of the salt), and adding two drops of this to 3 or 4 c.c. of cerebrospinal fluid withdrawn at the time of operation, and then reinjecting the mixture. He found that by this simple procedure the cocaine solution was almost entirely deprived of its toxic action (headache, nausea, etc.), while the analgesic action was not affected. He reported a number of cases illustrating the efficacy of this method.

Treatment of Urethral and Œsophageal Strictures by Linear Electrolysis.—Dr. J. A. Fort of Paris presented an exhaustive communication on the subject, giving in extenso the history of fifty cases. These were divided into two groups: the seventeen cases in the first group were seen between 1889 and 1902 inclusive, the thirty-three in the second group were treated during the present year. In the first group were five cases of stenosis of the œsophagus and twelve of urethral stricture, four of the latter being complicated by gleet; all were cured. The second group comprised twenty-three cases of simple urethral stricture, eight of urethral stricture complicated by gleet, and two of œsophageal stenosis; of the latter one was cured, in the other, a cancerous stricture, there was such marked improvement that it was possible for the patient again to take nourishment in the natural way. The urethral strictures were all relieved, but in some cases the patients passed from under observation before sufficient time had elapsed to warrant the assertion that a definite cure had resulted. From his experience with these and many other previously reported cases the author felt himself justified in concluding that linear electrolysis was preferable to internal urethrotomy in the treatment of urethral stricture and to gastrotomy in that of stricture of the œsophagus, provided, of course, that the latter was not absolutely impassable.

Indications for Surgical Intervention in Affections of the Stomach.—Dr. S. Cardenal of Barcelona presented a communication with this title, of which the following were the conclusions: Surgical intervention is indicated (1) in all gastric diseases in which are unmistakably and definitely present the symptom complex called by the author the pyloric tripod (pain, vomiting, and, above all, gastric retention), even when no positive nosological diagnosis has been reached; (2) in every case of certain diagnosis of gastric neoplasm, especially when demonstrable on direct examination, even when the functional symptoms are few or absent; (3) in all doubtful cases in which the patient is rapidly emaciating, even when the gastric symptoms are obscure and in the absence of a positive diagnosis, since that is the only means of arriving at a definite knowledge of the condition present and of obtaining positive indications for medical and surgical treatment.

Renal Hæmaturia of Six Months' Duration Without Apparent Lesion.—Dr. Alberto Suaşez de Mendoza of Madrid reported this case. The patient was a woman, thirty-four years old, married, childless, who suffered for six months continuously from hæmaturia, being finally reduced to an extreme degree of exhaustion and anæmia. Interrogation revealed a history of syphilis contracted two years after her marriage, when she was twenty-seven years old; this disease was treated carefully for two years and was believed to have been definitely cured. The most careful examination revealed no cause for the nephrorrhagia. Israel having had the most favorable results from a simple incision into the kidney in a similar case, the author performed the same operation, but without any effect upon the renal hemorrhage. Finally, the patient's life being seriously threatened by the continual loss of blood, the author resorted to nephrectomy. Microscopical examination of the kidney revealed absolutely no lesion capable of explaining the occurrence of the hæmaturia. Subsequently the patient suffered from an obstinate syphilide, cured finally by calomel injections. In view of this fact, the author expressed regret that he had not made a faithful trial of antisyphilitic treatment before extirpating the kidney.

An Enormous Vesical Calculus.—Dr. Mendoza also reported a case of stone in the bladder in a woman thirty-two years of age. The calculus was removed by hypogastric section and was found to be of very large size, measuring 24 cm. in its largest diameter, and weighing 265 grams.

Epiploitis in Herniotomy.—Dr. J. Ortiz de la Torre of Madrid read a paper with the following conclusions: (1) Suppurative epiploitis may occur as a complication of resection of the epiploon in hernia. (2) The diagnosis of the condition is simple, coming on as it does ten or twelve days after the operation with fever, pain, and swelling of the remaining portion of the epiploon. (3) Its course is very slow and is apt to be attended with the formation of abscesses, the pus passing in the direction of the intestine or the abdominal wall, and resulting in the formation of adhesions and the walling off of the original focus of disease action. (4) The only treatment indicated is that directed to relief of the pain, the expectant plan being followed in regard to the suppuration. (5) As a preventive measure it would be desirable to devise some method whereby the bleeding from the cut edges of the epiploon could be arrested without a resort to buried sutures. Angiotripsy, for example, would be an ideal method for the avoidance of infection.

Leucocytosis in Appendicitis.—H. Goetjes says that a maintained total count of from twenty to thirty thousand signifies the presence of pus complications which might cause a hyperleucocytosis can be excluded. A normal or subnormal total count gives a bad prognosis when present in an appendicitis which shows marked clinical symptoms. These statements apply only to those cases in which the appendix condition is circumscribed. If a diffused peritonitis is present the significance of the total count becomes much reduced, except that the higher the figures the more favorable the prognosis.—*Munchener medicinische Wochenschrift April* 28, 1903.

AMERICAN MEDICAL ASSOCIATION.

Fifty-fourth Annual Meeting, Held at New Orleans, La., on May 5-9, 1903.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

THIRD DAY—THURSDAY, MAY 7.

Sarcomatous Degeneration of Myomata.—Dr. T. S. CULLEN of Baltimore read this paper. He said that sarcomata might develop in all the varieties of myoma. They were developed from both the connective tissue and from the muscle fibers. Two varieties were from the muscle fibers, spindle and round cells. In some cases it was practically impossible to trace the development from myoma. He did not think it advisable to split the uterus when it was to be taken out if it could be removed as a whole when sarcomatous degeneration was present.

Dr. CLARK, in discussing this paper, said that it gave evidence that the indication for radical treatment in myoma was greatly increased. He did not know how far we dared to preserve the uterus, after what the author had just said.

Dr. CULLEN, in conclusion, said that he did not know the exact percentage of cases in which degeneration took place, but thought that it was between 1½ and 2 per cent. He advocated early operation in all cases of myoma, and that myomectomy should never be done unless there was a patent tube.

Ectopic Gestation: Inhibited Tubal Peristalsis a Cause; Report of a Case, with Remarks.—Dr. O. G. PFAFF of Indianapolis read this paper. He said that the peristaltic function of the tube was not generally appreciated, while too much stress had been laid on the importance of the ciliary wave. A great many cases occurred in which the tubes had not been previously infected. The tube was an excretory canal and, like the ureter and gall-bladder, had the power of peristalsis. The ciliated epithelium did not always have propulsive force. The ciliated cells acted as a soft, velvety bed, upon which the ovum rested, and the latter was moved along the tube by its peristal ic action. A case was reported in which the tube had become bound down and peristalsis could not take place at the time of ovulation, and there resulted a tubal pregnancy.

Dr. CARSTENS of Detroit said that one of nature's methods to prevent tubal abortion was to cause adhesions of the tube to the rectum, bladder, or pelvic wall.

Dr. DUDLEY said that it was known that many women became pregnant with the tube bound down, and that the cilia played a more important part than was formerly recognized. He thought that the diaphragm also played an important part in the movements of the ova to the uterus. Tubal pregnancy depended upon the patency of the tube.

Dr. Pfaff, in closing, said that tubal pregnancy might take place even in a healthy tube

Non-absorbent Gauze: The Proper Material for Tamponades for Hemorrhage, with Special Reference to Obstetrics.—Dr. R. W. HOLMES of Chicago read this paper. After the author had gone into the history of the various kinds of gauze which had been used to stop hemorrhage taking place after the delivery of a woman, he remarked that the absorbent gauze which was now in vogue for the prevention of this calamity and for its treatment was entirely improper for carrying out the idea intended for it. The original gauze of Lister was non-absorbent. It was one of the normal functions of the uterus after delivery to bleed, and the hemorrhage was best stopped by means of some sort of a non-absorbent gauze, as it had more capillarity than absorbent gauze. It had one-sixth the capillarity with water as had absorbent gauze Paraffin, when incorporated in gauze, delayed coagulation; hence, gauze prepared with it was of little or no use. The writer had used gelatin gauze on several occasions with success. Chianisol was the best hæmostatic to use along with non-absorbent gauze.

Dr. BACON of Chicago remarked that absorbent gauze was not a drainage; wicking should be used if one wished to obtain drainage. The impregnation of gauze with a hæmostatic was more important than the use of some non-absorbent material. In postpartum hemorrhage the fundamental thing was to stimulate contraction of the uterus and thereby hasten the coagulation of the blood.

Dr. W. P. MANTON of Detroit said that absorbable gauze answered every purpose, as it permitted the blood to coagulate in its meshes, and thus assisted coagulation elsewhere.

Dr. EFFA V. DAVIS of Chicago held that the chief thing was rather the prevention of hemorrhage, and this could be most easily done if one were careful to look into the history of the patient as regards the richness of her blood and as to whether there had been present before pregnancy a chronic inflammation of the walls of the uterus.

Acute General Staphylococcus Infection through the Puerperal Breast.—Dr. W. P. MANTON of Detroit read this paper. He said that since the advent of aseptic methods, general infection through the puerperal breast had been a rare occurrence, although normal human milk contained pus-forming bacteria. The object of the author's paper was to direct attention to a treatment which had been in vogue for some time, and which had been lauded in all the textbooks on this subject, viz., the massage of the breast in engorgement and beginning mastitis. This procedure was liable to produce general staphylococcic infection. The author reported a case of this kind with abscess formations in the breast after massage, and in which there developed later abscesses in the other parts of the body. These abscesses contained the same bacteria that were found in the abscesses in the breast. This was the only case that had been reported in the literature. Distension and turgescence of the breast should be treated by other means than massage.

Dr. JAIMESON of Detroit said that he had never seen a similar case, and believed that it was unique.

Dr. BACON of Chicago said that distinction should be made between beginning lactation and infection. In the latter condition there was always an elevation of temperature, so that the diagnosis should be most simple. Massage should not be made toward the nipples, but outward toward the axillary and subclavian arteries; in fact, he believed that massage was indicated in but few of the cases of this variety.

Dr. Manton said, in closing, that he was sure that general infection after these cases was more common than was generally supposed.

Destructive Sterilization by Cataphoresis in Cancer of the Uterine Cervix.—Dr. G. BETTON MASSEY of Philadelphia read this paper. He said that a large proportion of failures to cure uterine cancer, especially that of the cervix, was due to the implantation of the cancer cells in the cut surface of the wound made in the primary operation. This difficulty had been obviated by the invention and application of the thermocautery and other such operating electrical and thermic instruments, together with the method of driving into the tumor and the surrounding tissues a nascent salt of mercury The time required to destroy an averaged-sized cancer of the cervix with a current of five to six hundred milliamperes was from a half hour to two hours. The slough made in this burning operation would come away in any where from ten da s to two weeks. The best results were obtained in the employment of cataphoresis by a combination of both zinc and mercuric salts The after-treatment was expectant.

Dr. MOODY of Alabama said that the essayist's paper was worthy of more consideration than the section was evidently giving it. Where tumors could not be removed with the knife, this method would be of great value, in

his opinion, in the alleviation of many of the great and annoying symptoms experienced by these patients.

Dr. Massey, in closing, said that his method had been tried in seven cases recently, with one absolute success in a case in which he had had the opportunity of treating the patient before she had undergone any sort of cutting operation. The other cases were of a secondary nature, and all of them had been subjected to the knife and had come to him for treatment of a recurrence of the primary condition. He was very much surprised that, in view of the many failures that surgeons had had, that his method of treatment should not be taken seriously and given a fair trial, for such it deserved. One case which he had treated by his method had died from septic peritonitis at the end of six days.

Advisability of Vaginal Exploratory Puncture and Cœliotomy in Doubtful Diagnosis of Diseases of Female Genital Organs, with Cases.—Dr. C. B. Theinhaus of Milwaukee read this paper. He said that when cases were very doubtful, especially in hard tumors, the diagnosis between fibroids and malignant tumors was not always easy. Where there were fluctuating tumors the diagnosis must be made between long-standing pus accumulations, with perhaps a slight rise of temperature in the afternoon, cysts and extrauterine pregnancy. The author mentioned a case in which, on first examination, he thought that he had to do with a fluctuating tumor on the posterior portion of the uterus. He diagnosed it as a fibroid and advised immediate exploratory puncture. The patient objected and would not consent until about three months later, when, on making the puncture in the cul-de-sac of Douglas, he found that the large fluctuating mass was not fluid, but was a very soft, round-cell sarcoma, and that operation with a hope of cure was useless. In every case in which the diagnosis was doubtful, exploratory vaginal puncture should be done as soon as possible to clear up the diagnosis. At this time the operator should be prepared to do any operation which might be indicated, even to the extent of opening the abdominal wall and doing any sort of an operation that the case demanded. The operation was not original, but had been first done by Summers of New York City.

Dr. Stacey of Texas said that the operation was a good one for the occasional operator.

Dr. Craig of Boston thought that if there were pus present as high up as the author had said, he would reach with his exploratory puncture to the vaginal wall, and there would be a clear indication—in fact, a positive one—for abdominal work, and not, as the author had said, for operation by the vaginal route.

Dr. Carstens said that he believed in all that the essayist had said in regard to the procedure, but he would call the operation vaginal cutting and not puncture, for he believed that the incision should be a large one, anywhere from three to four inches, according as the condition demanded.

Dr. Theinhaus, in closing, said that it was never good practice to drain pus through the abdomen; in every such instance vaginal drainage should be employed.

Conservative Surgery of the Sclerotic Ovary.—Dr. H. O. Pantzer of Indianapolis read this paper. He said that ovaries of this variety were generally removed by operators of to-day because of the fact that they were considered to be entirely functionless and necessarily harmful while they remained, inasmuch as they were the source of painful and other disagreeable symptoms. On the contrary, the author believed that not all of these ovaries should be removed, but that conservative operations could undoubtedly be done on them with great benefit and relief of symptoms, besides permitting the retention of the function of menstruation and a possible subsequent pregnancy on the part of the patient. The author had had a case of a very much run-down woman in whom the abdominal walls were thin and poorly nourished, so that on vaginal examination it was possible to make out that the ovary on the left side was large and sclerotic. The broad ligament on the right side was contracted, and had pulled the uterus toward it, causing a slight backward displacement of that organ. The ovary on that side was also enlarged and hardened. The patient, though married for some years, had never become pregnant, but was most desirous, as was her husband, of having a child. The writer decided upon operation, and after he had got into the abdominal cavity decided to attempt to retain a portion of the right ovary. The left ovary was extirpated, but a wedge-shaped piece was taken out of the right ovary and part of its surface was pared off. The operator did not cover the raw surface, but simply dropped the ovary back into the abdominal wound, and closed the incision. The recovery of this patient was slow, but progressive. Two years later she became pregnant, and was delivered at full term of a nine-pound child.

Dr. Dudley, in discussing this paper, said that ordinarily one considered it good surgery to remove all such ovaries, inasmuch as the normal functionating tissue was supposed to have degenerated into scar tissue. But the conservatism practised by the essayist should show the profession at large that not in all cases could this dictum be held as true.

SECTION ON SURGERY AND ANATOMY.

THIRD DAY—THURSDAY, MAY 7.

Sunshine and Fresh Air Versus Röntgen and Finsen Rays in the Treatment of Tuberculosis of Bones and Joints.—Dr. De Forest Willard of Philadelphia read this paper. He said that these factors, together with good food, were invariable agents when combined with fixation of the joint in the contest with tuberculous infection of the hard tissues. Patients lying in bed should be subjected, on all possible occasionsl to the direct influence of the sun's rays, and to this end all hospitals should be provided with solaria and roof gardens. The diseased joints should be exposed to the direct rays of the sun, the patient's head and eyes being protected suitably. It might be well to cover the areas with blue glass, so as to enable the easier passage of the ultra-violet actinic rays. Local medications of the iodine group should be freely employed. Tent life, or any form of out-door existence, was advantageous in these classes of patients, although he thought that the improvement, often noticed to be so out of proportion to one's expectations, was due largely to taking the patient from an environment of starvation. It was just as important, he said, to establish sanatoria for the segregation and treatment of cases of tuberculosis of the hard tissues as of the soft. The sun's rays employed directly were more effective as curative agents than when concentrated by lenses. The electric rays were desirable in the absence of sunlight. The actinic and the *x*-rays were both apparently helpful in the treatment of tuberculosis, but five years at least would be required before we were able accurately to know their worth.

Epithelioma Under the X-Ray: A Preliminary Report.—Dr. J. Clark Stewart of Minneapolis presented this paper. He described in detail a remarkable case of extensive involvement of the hand, which lent itself very well to histologic investigations. From the numerous sections cut, he had made the following observations: Fat degeneration was marked in all sections immediately after the beginning of the treatment. This never occurred in epitheliomata when undisturbed. This deposit, as shown by osmic acid, was most marked in the nuclei and in the periphery of cells surrounding the pearls. The second important change noted was the rapid and extensive vascularization of the part which normally contained no vessels worthy of mention. This should not be confused with the formation of granulation tissue. These vessels were first filled with red-blood cells; later they were displaced and the vessel was packed by leucocytes. The final result, just prior to entire destruction, was the formation of a fine reticulum filled with polymorphonuclear

leucocytes and refuse which had undergone hyaline and other degenerations. The further history of the case showed a very important thing, *i. e.* that while the growth was destroyed, where it was directly exposed to the rays, it grew with such rapidity in places where it had been protected simply by the thickness of the skin as to necessitate extensive maiming operation.

Dr. H. A. Christian of Boston, in opening the discussion, said that too much credence should not be placed upon the supposed presence of fat when the demonstration consisted solely in the use of osmic acid, because it had been shown that many other substances turned in the presence of this reagent.

Dr. Edward H. Nichols of Boston said that the cases reported as having been discharged cured must be received with caution, because the mere skinning over and melting away did not by any means signify a cessation of the process It was probable that the action of the rays consisted simply in their mild caustic power. Furthermore, it should not be forgotten that there were numerous cases recorded in which undoubtedly the rays had actually caused epitheliomata. Thus it would be seen that they might alike do great good and incalculable harm.

Dr. John Ridlon of Chicago felt that very little of value could be found in the treatment of tuberculous joints by the *x*-and other rays; in any event they could never become anything more than superficial assistants to the standard treatment of fixation and extension.

Dr. F. B. Lund of Boston said that facial epitheliomata were known in many cases to be non-malignant. It was not, therefore, surprising that many of them might be cured by various rays, just as they would have been cured by agents possessing a similar caustic power. He urged that these new therapeutic agents did not justify the laying aside of the knife for the treatment of malignant skin lesions any more than in the case of the caustic pastes. At best they might only be considered aids not agents.

Dr. Willard said that all he desired to show was that light and its health-giving associates, food and air, were very essential, both locally and constitutionally, in the treatment of tuberculosis of the hard parts.

Varix of the Inferior Mesenteric Vein Complicated by Chronic Ulcerated Colitis.—Dr. John E. Summers, Jr., of Omaha, detailed the history of his operations upon this most extraordinary case. It was that of a man who had suffered for years from chronic ulceration accompanied by prolapse of the sigmoid. For a long time he contented himself with dilating the sphincter and washing out the colon with astringents. This failing, he did a left inguinal colostomy, and was astonished to find an enormous varix of the vein and all its branches. He therefore closed the wound without opening the bowel, and made an exploratory laparotomy above to determine, the cause of the varix, but failed to find it. He, however, performed gastroplication and Morrison's operation with some improvement. Upon the case relapsing, he did a right inguinal colostomy, with the intention of putting the parts at rest, and irrigated feebly. The patient promptly gained twenty pounds in weight. Having learned on the fifth day how to wash himself out, this procedure caused him very little trouble.

Congenital Dislocation of the Radius.—Dr. Charles A. Powers of Denver read this paper. The subject was a boy of thirteen in whom the upper left extremity had been congenitally shorter than the right. The forearm was fixed in pronation, supination being impossible. The left radius was dislocated upward, forward, and outward on the anterior aspect of the humerus. The literature did not give great encouragement as to operation.

Acute Epiphysitis of the Head of the Femur Causing a Condition Simulating Congenital Misplacement.—Dr. John P. Lord of Omaha read this paper. He said that his experience led him to believe that there were more of these cases than was generally supposed, many of them being mistaken for coxitis. This should, however, not be the case, because every case of epiphysitis which had gone on, as was so often the case, to an almost complete destruction of the head and neck showed scars from previous rupture or operation. *X*-ray photographs of the part showed the deficiency of bone and enabled a positive differential diagnosis between coxitis, epiphysitis, and congenital dislocation to be made. The most important point in the treatment of this well-nigh hopeless condition consisted in maintaining abduction at any cost.

Necessity for More Care in the Treatment of Skull Fractures.—Dr. W. H. Earles of Milwaukee presented this paper. He said that one could not be too careful in the treatment of these cases, and that the assumption should be that every case of contusion of the scalp was a fracture. Lack of cleanliness in fractures of the cranium was fraught with the utmost danger.

Epispadias: Report of a Case Treated by Modification of Caulwell's Operation.—Dr. James Bullitt of Louisville read this paper. He said that Caulwell's operation had not gained the prominence which it deserved, and that it was a pity it should have been neglected by the textbooks hitherto. In technic it was simple, consisting in transplanting the new urethra to its normal position by a free and careful dissection of the mucous membrane and a separation of the corpora cavernosa. Should the wounds heal by first intention, the work was completed in ten days.

Dr. Parham of New Orleans said that Cantwell's operation was without doubt the best and easiest, the corpora cavernosa being frequently separable without the use of the knife.

Dr. Fenner of New Orleans had noted with surprise, in performing this operation, the ease with which the technic could be carried out. An unfortunate experience had shown him the absolute necessity of using absorbable ligatures. The perineal buttonhole should invariably be made.

Cicatricial Ankylosis of the Jaws: A Contribution to Its Operative Treatment.—Dr. Rudolph Matas of New Orleans presented this paper. He said that while such conditions did not involve life, they impaired physiologic usefulness. He reported the case of a man twenty-seven years of age, in whom cicatricial osseous trismus had resulted as the result of repeated mercurial stomatitis in early childhood. Not even a knife-blade could be passed between the teeth. The individual had subsisted entirely upon liquid food, but had learned to use tobacco, having, indeed, suffered from the formation of several osteophytes, which were composed largely of tobacco derivatives. The development of the lower jaw had been so retarded that it was of the infantile type. He had operated from without, producing at the first sitting a marked condition of macrostoma, and substituting for the lost musosa of the mouth skin from the cheeks, which was stitched to the margins of the gums. The relief not being complete, a long skin flap was added from the neck. The left condyle of the jaw was excised and cuneiform excision of the angle of the jaw was practised. The recovery, though not cosmetically successful, was functionally good.

Further Contribution to the Surgery of Undescended Testicle.—Dr. Arthur D. Bevan of Chicago read this paper. He said that cryptorchidism was a much more common condition than usually supposed. The cases probably numbered one in 500, producing mental and physical symptoms. It was one of the most important conditions one could be called upon to treat, and was almost always accompanied by hernia. Among other reasons for operating was that if left in its exposed position malignancy from traumatism, as well as pain from the same cause, was very likely to ensue. His most recent investigations had taught him that the spermatic vessels could be ligated without damage to the testicle. The explanation of this was to be found in the freedom of

the anastomosis with the vessels of the vas. Recently he had found a few cases in which he had been unable to keep the testicle in the scrotum without considerable tension. Under these conditions it was absolutely safe to cut everything except the vas and its vessels. These never were too short. It was always the spermatic vessels which caused the trouble. He advised operation from the sixth to the tenth year.

Dr. Bartlett of St. Louis said that because of the sterility of these individuals it was probably better to remove the organ entirely, unless they were operated upon after puberty, because to them the only function of the testicle was its internal secretion.

Dr. Rodman of Philadelpha believed that if boys were operated upon at an early age the organ might not alone be saved for its internal secretory function, but for that of reproduction as well.

Surgery of the Urinary Tract in the Female.—Dr. J. B. Murphy of Chicago discussed pyelonephritis and hydro-and pyonephrosis. Some important points in the surgery of the kidney were that we possessed four times the necessary amount of kidney tissue to do the needed work. When a portion of the excess was removed, the remainder was stimulated to grow, there being a most remarkable vital relationship between the two organs. He made an eloquent appeal for conservatism in the treatment of abscess of the kidney, saying that it should be given precisely the same treatment as collections of pus elsewhere. He believed that wholesale excision of kidneys had been too widely practised. Pyonephrosis was invariably a sequel of hydronephrosis, which itself was merely a symptom. The cause should be removed. Clinically, it could be divided into three regions, viz.: (1) Obstruction in the the upper one-fifth of the ureter; (2) obstruction in the middle three-fifths, and (3) obstruction in the bladder attachment of that tube. The treatment of renal cysts should be based upon a recognition of the fact that they are lined with epithelium. He preferred opening the pelvis to the trans-renal route. He would do vertical anterior colpotomy with section of the bladder for the removal of stones and papillomata when lodged low down in the ureter.

Dr. Matas of New Orleans said that the most important aim of surgery was to preserve the organ when so doing was not dangerous to the organism. He suggested the use of retrograde drainage by passing a tube from the back through the split kidney, down the ureter, and through the bladder and urethra.

Dr. Martin B. Tinker of Baltimore said that Americans should be proud that their surgeons were the first to do nephrectomy; that they had removed the first stone and done the first decapsulation.

Tuberculosis of the Mammary Gland.—Dr. A. H. Levings of Milwaukee said that although this condition was an extremely rare one it seemed probable that a number of the cases of so-called carcinoma were probably of tuberculous nature. The condition was most frequent during menstrual life in single women. It was often primary, and might involve both sides.

Officers Elected.—The following officers were elected for next year:

Chairman, Charles A. Powers of Denver, Col.; *Secretary*, E. Wyllis Andrews of Chicago, Ill.; *Member of House of Delegates*, W. J. Mayo, Rochester, Minn.

SECTION ON SURGERY AND ANATOMY.

FOURTH DAY—FRIDAY, MAY 8.

Clinical Report of Fractures of the Upper Third of the Femur.—Dr. Seton of New Orleans presented these remarks. He thought that too much attention was ordinarily given to extension, and too little to fixation. The mistake that had been made in the past, when plaster of paris had been used, was in not carrying the cast far enough up on the body. Too much plaster was applied to the distal fragment—too little to the proximal. He had found that by adding a shell of silicate bandages, better results could be obtained. He advised the application of the plaster-of-paris dressing as soon after fracture as possible.

Dr. Grant of Denver hesitated to apply so absolutely unyielding a dressing as plaster of paris until after the primary swelling had subsided.

Dr. Brandon of Tennessee advocated a sort of three-angle splint for fracture of the femur in children, which was similar to that commonly used for adults.

Dr. Draper Maury of New York reported having made seme experiments in connection with the use of dextrine in the proportion of 10 per cent. by volume with plaster of paris as an improvement upon the "glass" bandage. If applied as a shell of one or two thicknesses of crinoline over the ordinary plaster cast—which had been made much lighter than usual—it would create a cast of almost adamantine hardness; of about two-thirds the usual weight and of nearly one-third greater durability. It was somewhat slow to dry, and a convenient method of expediting this was to heat it with a common painter's gasoline torch. The porosity was reduced by the dextrine, but this could be more than compensated for by the cutting of fenestra at frequent intervals.

The Closure of Wounds.—Dr. Miles F. Porter of Fort Wayne, Ind., read this paper. He made no claims for priority in the method which he detailed in full, but felt that the question was still so very unsettled and of so very great importance as to demand the attention of all. Under all conditions, save when tension and sepsis existed, through-and-through sutures should be discarded for adhesive plaster strips. These, he said, could easily be kept sterile for an indefinite period by keeping them in an atmosphere of formalin. Stitch abscess formation was due to three factors—the injury of the tissues, the presence of germs, and the failure to obliterate dead spaces. All these conditions were ideally met by the use of adhesive zinc oxide plaster strips. A well-rolled wad of absorbent gauze placed on either side of and parallel to the wound obliterated the spaces—in the absence of undue tension—there were no traumata made by needles—no foreign matter of questionable sterility was placed in the tissues. The method was particularly useful in operations about the face, as hare-lip. Perfect coaptation, as shown by the invariable soaking of the gauze dressings in the several hundred cases in which he had used it, was not incompatible with perfect drainage.

Dr. Morton of California said that it was the abdominal fasciæ which gave strength to the part; which, rather than the muscles, held the viscera in. No number of gauze wads could, in his opinion, coapt the severed fasciæ. Therefore the method could never appeal to him as being based on practical grounds. In wounds of the extremities, however, particularly in amputations where drainage was so necessary and after removal of varicose veins, it was admirable.

Dr. Porter, in closing, said that he wished it to be distinctly understood that he used and advised the method only in those wounds in which there was no infection and no great degree of tension.

Operative Treatment of Ophthalmic Goiter.—Dr. T. C. Witherspoon of St. Louis presented this paper It was a valuable report on the after-history of the nine cases upon which he had operated since 1895, together with a description of methods used. In all but one he had performed hemisection of the most prominent lobe of the thyroid. In that single case he had done Jonnesco's operation—removal of the upper and middle cervical sympathetic ganglia. The result had been poor, and he was discouraged from making further trials with this technique by the failures of others. So little was known of the pathology of exophthalmic goiter that it was very difficult to say when to operate. Every surgeon had asked himself this question in vain. Some very grave cases improved markedly under strictly medical care. He

had noted, however, that this gain was always transient—that the case fluctuated only, gradually going from bad to worse, unless some surgical steps were taken. This being the case, it seemed but fair to suppose that the only hope which could be held out to these unfortunates lay in advising early operation. The technique of hemisection of the gland he described as follows: He advised longitudinal free incision along the anterior border of the sternomastoid rather than the inferior transverse U-shaped incision of Kocher, because the latter gave only limited room, and this was a desideratum because the misplaced and dilated thyroid vessels were very troublesome to tie in any case. The superior thyroid could usually be secured without much trouble, but the inferior vessel was sometimes most difficult of access. The most important aid in effecting ligation lay in splitting the capsule in the line of the skin incision, and in separating it from before back, and from without in. Thus, the recurrent laryngeal nerve was exposed and avoided, and the vessels secured between the gland and the capsule. He felt that anyone who attempted to remove the mass encapsulated would, sooner or later, lose his patient. These cases could stand no hemorrhage whatsoever, so he considered any blood-saving technique as of ultra importance. The isthmus, to which was usually ascribed great hemorrhagic properties, he had found of very little annoyance—it required but ordinary treatment in its sectioning. He considered the use of one-tenth per cent. cocaine for infiltration a safer anæsthetic than chloroform or ether.

Dr. Grant of Denver, in opening the discussion, said that he agreed with the author in opening the capsule before attempting to tie the arteries. Patients suffering from Graves' disease had but little resisting force, and particularly if their hæmoglobin was below 50 per cent. they should never be given a general anæsthetic. He always prepared his patients by absolute rest in bed, and, if indicated, by the exhibition of strychnine.

Dr. Rixford of California said that the problem of operating in these cases was complicated by the fact that there seemed to be two types of the disease—that in which the goiter was primary, the symptoms following, that in where the symptoms appeared before the tumor. Operation seemed to give the brighter outlook in the first class, since they are usually more or less simple adenomata. The skin of these patients was very tender and absorbed very quickly. Hence strong antiseptics were contraindicated and, because of a low resisting power, sepsis was very apt to be fatal. For cosmetic reasons he preferred the transverse incision, but if the tumor were large, it called for the vertical opening. He felt that the outlook for this operation was good.

Dr. Horsely of Texas said that there were two very distinct views held concerning the origin of exophthalmic goiter. By one the symptoms were considered the result of sympathetic nerve disturbance, by the other they were ascribed to adenomatous dysgraciæ. Naturally, no truly scientific surgical work could be done, until this moot pathological point were settled. He thought that we should be most careful not to hope for too much from operative intervention, that the apparent improvement might be due wholly to the nervous shock inflicted by the operation.

Dr. Witherspoon, in closing, said that all cases should be operated on in the event of medicine failing to give help—that the operation of choice was hemisection of the thyroid rather than removal of the sympathetic ganglia.

Subcutaneous Injections of Paraffin for Deformities of the Nose.—Dr. F. G. Connell of Colorado read this paper. He spoke of the widening of the field in which this treatment might be used, and of its almost absolute safety as regards life. The desiderata were to avoid too much heat and tension. He advised the use of 1 per cent. cucaine of a screw instead of ordinary plunger for the syringe, the introduction of a limited amount at a time, and the leaving alone of the patient for at least twenty-four hours after operation. He concluded that Corning of New York was the first to advise the use of non-absorbable oils, that the work was still in experimental stage, that its introduction for the correction specially of certain nasal deformities would be wide, and that general anæsthesia was, as a rule, unnecessary.

Dr. Norton of California said that he had found sperm oil a very useful medium for keeping his paraffin melted, and at an even temperature of 109° F. He thought that the amount which it was safe to introduce depended entirely on the degree of tension which was produced, and this was to be estimated by the whitening of the skin over the site of injection. He showed an admirable series of photographs of microphotographs of sections of paraffin, which had been allowed to stay in the tissues from one to five months. The series, each removed one month apart, showed that the paraffin by the sixth month was not alone encapsulated, but entirely absorbed. It thus was proved to be the analogue of the primary blood clot which undergoes organization.

Dr. Mayo of Minnesota said that in order to be able safely to inject enough paraffin to do any good it might sometimes be useful to undercut dense scar tissue with a cataract knife, or, as McDonald had said, to stretch the part a few days previously by the forceful injection of salt-solution.

Abscess of the Spleen.—Dr. Walter M. Spear of Rockland, Me., presented this report. He detailed a case of this condition, which his investigations led him to consider to be more frequent than was generally supposed. The patients generally gave a history of malaria or typhoid fever. He concluded that the condition was not to be diagnosed save by exploration, but that it occurred with sufficient frequency to justify its being considered in all doubtful cases. The only treatment lay in splenectomy.

The Choice of Anæsthetics.—Dr. Mellish of Texas read this paper. He said no one was justified in using one anæsthetic to the exclusion of another. He believed that this question could be settled only by the skilled anæsthetist, but that, in general, chloroform should never be used when the anæmia is as low as 50 per cent., because ether is less destructive to the red blood cells. Gas, or gas and oxygen, was the anæsthetic which approached more nearly than any other our ideal, but in some cases absolute relaxation could not be obtained by its use. Compression of the phrenic nerve would often stop vomiting during the operation, and for its after control water should be given freely both just before and after operation. It should always be given liberally by rectum, for it affords the surest way of eliminating the drug. Ether was dangerous in arteriosclerosis; chloroform in anæmia and myocarditis.

Dr. Moore of Minnesota said that he had used chloroform for twenty years in 95 per cent. of his cases and had had no deaths. This proved that it was not the drug but the skilless giver who killed the patient.

Dr. Tinker of Baltimore said that in any discussion on anæsthesia the local methods of introducing it should have important consideration. At the Hopkins they had been convinced of its adaptability and safety. There were three conditions necessary to its successful employment—the patient, above all, should wish for it—the operation should be done slowly, 1 per cent. cocaine should be introduced into nerve trunks of all nerves leading to the part—$\frac{1}{6}$-gr. morphine should be given one hour before; $\frac{1}{6}$ before beginning the operation, $\frac{1}{6}$ during it.

Dr. Ochsner of Chicago said it was important in treating threatened death from chloroform to first compress the ribs heavily, so as to expell all contained chloroform, then to begin artificial respiration. Otherwise the first effects of raising the arms was to give the patient a big dose of chloroform by suddenly diffusing it throughout the lungs.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

One Hundred and Seventy-ninth Regular Meeting, Held on Friday, March 6, 1903.

JOSEPH D. BRYANT, M.D., PRESIDENT, IN THE CHAIR.

Nasal Deformity Corrected by Paraffin Injections.—Dr. ROBERT F. WEIR presented a young man upon whom he had operated by this method. As the result of a badly depressed fracture, the condition known as saddle-nose had been produced, and in order to correct this deformity the paraffin injections were made directly underneath the skin, with an excellent result. The paraffin was dissolved in three parts of olive oil. The speaker said that the paraffin was now being very extensively applied, not only in deformities of the nose, in which locality he had employed it five times, but also in other regions of the body. It had been injected for the purpose of improving the appearance of scars and depressed cicatrices, even in the small depressions following smallpox. It had also been used as a plastic artificial vitreous after enucleation of the eyeball, to support an artificial eye, and more recently it had been employed to produce narrowing of the outlets in certain cases of fecal or vesical incontinence. The procedure was still of such recent origin that it was impossible to say whether the correction of these deformities would be permanent, or whether the paraffin would in time become absorbed or undergo some change. In making the injections, a moderately large-sized hypodermic needle was necessary. In order to prevent the paraffin solution from solidifying too rapidly and thus choking up the needle, a drop or two of hot water should be drawn into the syringe after the paraffin, and the loaded syringe be kept in warm water at or above 104° until needed for use.

Dr. CHARLES STEDMAN BULL said he had used the paraffin in two cases in the orbit in which the eyeball had been removed, in order to make a better stump for an artificial eye, and in both instances it had worked extremely well. For the purpose of making the injections, he had used a hypodermic with a large barrel and a good-sized needle. It not frequently happened that after enucleation of the eyeball the orbital contents shrunk to such a degree that the artificial eye was not satisfactorily supported, and became very conspicuous on account of its false position and appearance. It was in that class of cases that the paraffin was now being used with much success.

The President, Dr. BRYANT, said he would be much interested in watching the ultimate result of the paraffin injections in the nose and elsewhere. Personally he had had no experience with this ingredient. In correcting deformities of the nose, he was very well pleased with the results he had obtained by the use of thin plates of celluloid, which could be properly bent and introduced underneath the skin.

Dr. WEIR said that in a case of fecal incontinence, which he recently had under his care, the patient obtained good control of the fecal outlet after half a dozen paraffin injections. The injections were made into the structures surrounding the anus.

Fracture Diastasis of the Humerus with Deformity Relieved by Operation.—Dr. WEIR presented a child, three years old, who, early in October, 1902, fell and sustained a fracture of the lower end of the left humerus. Following the accident, the child was unable to extend the arm, and upon examination, a bony projection could be made out just above the elbow. There was evidently a fracture diastasis with impaction and forward displacement just above the joint, and this was subsequently demonstrated by an *x*-ray picture. This would permit flexion only to an obtuse angle. Two weeks after the accident, the parts were laid open by an incision, and the fracture exposed and broken up with considerable force, the parts were then placed in their normal position and sutured together with chromicized catgut. The limb was put up in a strongly flexed position and the child made an excellent recovery. The motions of the limb were practically fully restored.

Dr. BRYANT said he thought an open operation was not only justifiable but often indicated in cases of fracture near a joint, like the one shown by Dr. Weir; otherwise, it might be difficult to secure proper apposition of the fragments, and the result would be unsatisfactory.

Some Unusual Cases of Appendicitis.—By Dr. ROBERT F. WEIR (see page 801.)

Dr F. P. KINNICUTT said he thought the suggestion of Dr. Weir's to add adrenalin chloride to the salin solution was a valuable one. What we wished to produce ofttimes by the saline injection, was to increase arterial tension, and the adrenalin should prove useful for that purpose. Three years ago, Dr. Kinnicutt said, he saw a case of primary carcinoma of the appendix. The patient was a girl of nineteen years, who had had a number of attacks of appendicitis; she was operated on in a quiescent stage by Dr. McBurney, and a condition very similar to that described by Dr. Weir was found. The specimen was sent to the Pathological Laboratory of the College of Physicians and Surgeons, and proved to be carcinoma. The operation was done three or four years ago, and the patient has remained perfectly well since. Shortly after the operation mentioned a primary carcinoma of the appendix was found in one of the subjects in the dissecting room of the College of Physicians and Surgeons.

Dr. WILLIAM M. POLK said that in order to eliminate the danger of leaving sponges or pads within the abdominal cavity, he had adopted a method which was first suggested to him by Dr. William T. Bull, and used, instead of pads and sponges, rolls of gauze which were three or four yards in length and about four inches in width, and made up of several thicknesses of gauze; the excess, which was not used within the wound, was held in roll outside by means of an artery forceps. Some years ago, Dr. Polk said, he removed an appendix in a patient at Bellevue Hospital which had become elongated by having been stretched over a post-peritoneal sarcoma which sprang from the lumbar glands. The appendix in that instance measured thirteen and one-half inches. In another case he recalled, bands about the appendix had furnished an opening through which a loop of small intestine, about two inches in length, had passed and become constricted, giving rise to symptoms very similar to those in the case reported by Dr. Weir. Last October, the speaker said, he had operated on a case in which a cystic condition of the appendix existed The appendix was three and one-quarter inches in length by three-quarters of an inch in width.

Dr. WILLIAM T. BULL said that, speaking from memory only, the longest appendix he could recall, was seven inches; he had seen perhaps, two or three of that length. Many years ago, at the New York Hospital, he saw an appendix which extended entirely across the brim of the pelvis from its usual point of origin at the cæcum to the sigmoid flexure, to which it was adherent. There was a direct communication between the lumen of the appendix and that of the sigmoid flexure. The organ was seven inches long. Six weeks ago, Dr. Bull said, he saw a third long appendix in a patient who presented unusual clinical phenomena. It was a first attack, and during the three days' illness preceding the operation the constitutional symptoms had been very slight; there was very slight pain and local tenderness, and the temperature had not risen above 99½° F. There had been, however, persistent vomiting, and it was because of that symptom that the operation was advised. The appendix was found to be seven inches long. It was slightly inflamed, and there was a moderate degree of stenosis at the cæcal end, while its tip extended upward very close to the usual seat of the

pyloric office of the stomach. Its situation and length apparently, had some bearing on the unusual clinical features of the case. Dr. Bull said he had no recollection of ever having seen a particularly short appendix, and only on one occasion had he failed to find the organ. That was a case in which the operation was done in the interval after the first attack of appendicitis, which was very severe and had lasted three weeks, and during which the appendix had probably been discharged through the abscess. He had never seen an instance of marked cystic dilatation of the appendix. In discussing the possibility of leaving a foreign body in the abdominal wound, the speaker mentioned a case in which a good-sized towel was left in the abdominal cavity. Its presence was discovered twelve days after the original operation, and after its removal the patient made an uneventful recovery.

Dr. Beverly Robinson thought that strychnine would be a more valuable addition to a saline solution than adrenalin, as we had a better knowledge of the action of the former than the latter. Many years ago, the speaker said, he had called attention to a possible danger attending the use of saline infusion *alone* in pneumonia, and Dr. Tyson of Philadelphia had recently brought up the same point in regard to hypoderm clysis alone,* namely, the danger of overdistending the right heart. The same danger attended the use of large quantities of saline solution in the veins by the surgeon, unless it was given after a severe hemorrhage in which there was collapse.

Dr. Bryant said that a few years ago he removed a cystic appendix, the diameter of which measured between one inch and an inch and one-half; its length was seven inches. It extended upward and backward, on the outer side of the ascending colon. The symptoms it had given rise to were chronic in character, but otherwise not unusual. In regard to the presence of a short appendix, the speaker recalled a case in which he had operated for a tumor in the iliac region, and at the usual site of the appendix he found nothing excepting a slight elevation less than a quarter of an inch long.

Dr. Kinnicutt said, in his experience there was invariably a rise of temperature after an intravenous saline infusion. He mentioned a case of poisoning by illuminating gas, recently treated in his wards at the Presbyterian Hospital, where an infusion of 800 c.c. of saline solution, introduced into the same opening through which the patient had been bled, was followed within an hour by a temperature of 108° F. This temperature did not occasion any particular discomfort so far as could be judged by the patient's appearance or the physical signs, and it dropped within an hour to 101° and the patient recovered. Regarding the significance of abdominal muscular rigidity, the speaker said there were undoubtedly cases of localized and even diffuse peritonitis in which this symptom was absent, although they were exceptional. He recalled such a case, which was in the wards of the Presbyterian Hospital two years ago. The patient was a woman, who was watched with the greatest care day by day. She was evidently suffering from sepsis, but its focus could not be made out. Drs. McBurney, McCosh, and others saw her, but it was decided not to operate. She died in the course of a week, and at the autopsy a gangrenous appendix was found. This evidently had been the cause of her septicæmia, but it had given absolutely no signs that could be made out during life; there had been neither muscular rigidity nor other symptoms pointing to the abdomen.

Dr. George L. Peabody said that the case reported by Dr. Kinnicutt showed that appendicitis might exist without giving rise to any of the usual symptoms of that disease. He thought the converse was also true, *i.e.* that the typical symptoms of appendicitis might be present, and still, upon operation, the appendix be found normal. He inquired whether any of the members had ever seen such a case?

Dr. Weir said he had not. In earlier years, before the present method of distending and examining the appendix were in vogue, it occasionally happened that a case was operated on in which the organ was apparently normal, but in those cases the lesion of the appendix was probably overlooked. The practical test was that subsequent to the operation, the patients remained free from the symptoms pointing to the appendicular trouble.

Dr. Polk said he could recall more than one case in which the gross appearances of the appendix were apparently normal, but upon distending it, a small ulceration and slight thickening of the mucous membrane were found near the tip of the organ.

Dr. William T. Bull said he supposed Dr. Peabody had referred to cases of acute appendicitis, and not to those which were operated on during the interval between attacks. The speaker said he could recall one case of supposed acute appendicitis which was operated on and proved to be typhoid fever, and he knew of one or two other instances in which the appendix was apparently perfectly normal, in spite of the symptoms.

Dr. Robinson said he knew of one case in which the abdominal symptoms had led to a laparotomy which revealed nothing.

A Case of Endarteritis Obliterans of the Central Retinal Artery.—Reported by Dr. Charles Stedman Bull. The patient was a man fifty-two years old who, in October, 1901, had an attack of right hemiplegia involving the arm and leg, from which he had made almost a complete recovery. In August of the following year he awoke one morning and found himself entirely blind in the right eye. He was positive that he had seen perfectly well the night before. He regained the vision of this eye in about four days, and he had no further trouble until March 1, 1903, when the sight in the same eye was again lost, excepting in a very small field in its supero-nasal quadrant. The ophthalmoscopic picture in this case, Dr. Bull said, was quite unique, as it showed total obliteration of all the branches of the central retinal artery. The sight of the other eye was not disturbed. The patient's heart action was feeble, but perfectly regular; there was no valvular lesion and no murmur. The urine had a specific gravity of 1016; it was a light straw color and about thirty-four ounces were passed in twenty-four hours. It contained about 2 per cent. of sugar and a trace of albumin; no casts. In 1901, at the time of his first attack of hemiplegia, this patient probably had an embolus of a cerebral artery which was not large enough to block completely the caliber of the vessel. The first attack of blindness was probably due to a thrombus in the central artery of the retina due to narrowing of its caliber by endarteritis. The subsequent attacks were probably due to recurrent attacks caused by the progressive arteriosclerosis, ending in the present picture of complete endarteritis obliterans.

Presentation of Specimens.—Dr. Weir showed the stomach and upper part of the duodenum from the case of perforated duodenal ulcer to which he had referred in his paper. The patient entered the Roosevelt Hospital forty-eight hours after his first sharp attack of pain, which was referred to the upper part of the abdominal cavity. He gave an indefinite history of having suffered more or less pain in the abdomen for two years. His temperature on admission was 104°. The physical signs were strongly suggestive of pneumothorax, and the case was regarded as such by the attending physician; Dr. Weir made a diagnosis of perforated duodenal ulcer, or possibly of a strangulated diaphragmatic hernia. For, upon auscultation, a sound was heard resembling that produced by air passing through a narrow orifice. An operation revealed a duodenal ulcer, through which gas and biliary fluids were escaping. This was duly sewn up and anterior and posterior drainage resorted to, but the patient only survived three days. There was no lesion of the stomach.

**The Journal of the American Medical Association*, November 15, 1902.

Dr. Weir said he mentioned this latter fact because Moynahan, who had recently written on this subject, had made the statement that he had never seen a duodenal ulcer which was not associated with a gastric ulcer.

Dr. KINNICUTT said that in a series of six cases of duodenal ulcer that had been under his observation and coming to autopsy, there was only one in which a gastric ulcer also existed.

Dr. ROBINSON said he had a case under observation which he suspected was one of ulcer of the stomach. An analysis of the stomach contents showed that about the normal amount of free acids was present. He inquired whether an approximately normal degree of acidity was to be expected in a case of gastric ulcer?

Dr. KINNICUTT, in reply to Dr. Robinson, said, according to the investigations of Ewald and other German observers, which were very thorough, the degree of acidity of the gastric contents was a very unreliable factor in cases of *duodenal* ulcer. In other words, there was no increase in the acidity in many cases.

Dr. PEABODY said that at some stage in the course of a gastric ulcer there would be increased acidity, but the latter was not infrequently found to be normal.

Echinococcus Cyst Attached to the Omentum.—Dr. POLK showed this specimen, in connection with the following history. The patient was a woman, sixty-six years old, with an intraabdominal tumor, which was situated about midway between the umbilicus and the crest of the right ilium. The patient had long suffered from fibromyomata of the uterus, for which a hysterectomy had been done. At one time at that operation, Dr. Polk said he had felt this tumor in the abdomen, and came to the conclusion it was a detached fibromatous growth which had drifted away from the uterus. Subsequently, it began to cause the patient some pain, and as she was anxious to have it removed, an operation was undertaken for that purpose. The tumor was found within the folds of the greater omentum, and after considerable difficulty in separating the old adhesions, it was removed. It was sent to the department of pathology of the Cornell University Medical College for examination, and Dr. James Ewing reported that it was an old sterile echinococcus cyst. It was globular in form, measuring 9x7x6 cm., and surrounded by a dense capsule, which in places was calcified. The contents consisted of brownish, gelatinous masses, somewhat resembling the daughter echinococcus cysts, but soft and gelatinous (almost diffluent) in consistency. The gelatinous contents failed to show any scolices, hooklets, or cholesterin crystals, but were composed of a mucinous material without structure, mixed with red cells. The capsule had four distinct layers: externally, there was a well-developed vascular layer; next came a layer of dense connective tissue becoming denser from without in and showing numerous calcific areas; next was a faintly lamellated layer of homogeneous material, and finally, a thin irregular layer of granular material. The first two layers were contributed by the host, the two latter by the parasite. Between these two portions were collections of enormously pigmented endothelial macrophages. The diagnosis of sterile echinococcus cyst rested on the gross appearance of the contents, the structure of the wall, which was typical, and the lack of evidence pointing to any other origin.

A Case of Chronic Productive Inflammation of the Omentum without Apparent Cause.—Specimen presented by Dr. POLK. The patient was a woman, aged forty-two years, who came under his observation in October, 1902. She complained of constipation, and a persistent pain on the left side of the abdomen from the free border of the ribs to the crest of the ileum. In appearance, the patient, though well nourished, was somewhat cachectic. Upon examining the abdomen, a flat, cake-like tumor was found extending from above the umbilicus nearly to the crest of the ilium. From the symptoms and the patient's appearance, the growth was regarded as probably malignant. The symptoms were as follows: In June last, while moving some furniture, she had a sudden severe pain upon the left side of her abdomen. The next day she was confined to her bed, and ever since she has had constant pain in this region. About the 1st of August she noticed a lump, and this gradually increased in size and in tenderness. On the 9th of September the pain became so severe, she called in her physician, who kept her in bed until September 30, when she entered the hospital. Her bowels, previously regular, became slightly constipated. She gave no history of syphilis, of tuberculosis, of gastric ulcer, of appendicitis, or disease of the gall-bladder, or pelvic organs, concerning all of which she was closely examined. She was admitted to Bellevue Hospital on September 30, and a careful examination revealed the tumor as described above. The diagnosis of probable carcinoma of the omentum was made. On October 11 she was operated upon, when it was found that a yellowish, flat, cake-like mass involved practically the whole of the greater omentum, and a small portion of the lesser; the lesser omentum, where it overlapped the greater, was attached to this tissue. This was the sole point at which any adhesions existed; in fact, the mass was entirely free from any evidences of old or recent surface inflammation; the vascular appearances were similar to those of the surrounding viscera. The mass was apparently about 5½ inches wide by 2½ inches thick at its junction with the transverse colon, and tapered thence to a thin, wedge-like margin at the border of the greater omentum. It did not implicate the wall of the intestine, but was in contact with it; there was, to all appearances, no thickening of the wall of the intestine. As it extended along pretty much the whole of the transverse colon, it was concluded to remove this part of the gut along with the growth; eleven inches, of the transverse colon was consequently taken out, the section being made an inch and a half beyond the point at which the thickening of the omentum ceased. The cut ends of the intestine were sutured together, and the abdomen was then closed with a small drain; this was removed at the end of four days. At the end of a week there was evidence of an intestinal sinus; this gradually closed, so that at the end of six weeks the patient was discharged in good condition. Her physician reported two days ago that she was in excellent condition. The following report regarding this case was received from Dr. Otto H. Schultze of the Pathological Laboratory, Cornell University Medical College: The specimen was found to consist of a section of transverse colon, with omentum attached. The latter presented a firm mass, about five inches in width, a little over four inches in length and about one inch in thickness. The mass was traversed in all directions by bands of grayish-white tissue, varying in width up to two m.m., which separated the adipose tissue into smaller and larger areas. The bands consisted of dense, fibrous connective tissue, and scattered throughout this tissue were smaller and larger areas of round-celled infiltration. Various stages of development, from young connective tissue cells to less cellular and more fibrous connective tissue, were presented. Many mast cells were present. The smaller vessels showed a swelling and proliferation of their endothelial cells; the larger vessels showed a proliferation of their sub-endothelial connective tissue in addition. In the intervening islands of adipose tissue minute areas of round-celled infiltration were present in varying number. Tubercle bacilli could not be demonstrated in sections stained by Weigert's method. Diagnosis, chronic productive inflammation. The point of interest to the reporter of the case consists not only in the nature of the growth and the mistake in the diagnosis which was made, but that, in spite of a careful examination of the various regions of the abdomen from which a chronic

productive inflammation might originate, he failed to find evidences of disease. Nothing was found in connection with either the stomach or the colon to indicate that the inflammation had originated within either of these structures.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 16, 1903.

	Cases.	Deaths.
Measles	392	16
Diphtheria and croup	366	44
Scarlet fever	380	18
Smallpox	..	..
Varicella	98	..
Tuberculosis	335	151
Typhoid fever	50	11
Cerebrospinal meningitis	..	..

A Stain for the Gonococcus.—Wahl describes a method which is so simple and rapid as to make it adaptable for office use. The stain used consists of:

Concentrated auramin solution (alcoholic) ....2 c.c.
Alcohol, 95 per cent.....1.5 c.c.
Concentrated thionin solution (alcoholic) .....2 c.c.
Concentrated methyl-green solution (aqueous) .3 c.c.
Water.....6 c.c.

This stain is ready for immediate use, and the smears should be immersed in it for from five to ten seconds. The gonococci are stained a reddish violet to black, the nuclei of leucocytes are a pale bluish green, the plasma is either colorless or light yellow, according to the thickness of the smear, and epithelial cells are yellowish green. Most cells occasionally are stained a lilac color, which, however, is always pale and cannot cause confusion with the gonococci. Urethral bacteria other than the gonococcus are either very pale or are not stained at all, a point of great assistance in differential diagnosis. A point of importance in practical work is that thin smears are not necessary, so that threads and mucous strings need not be flattened out but may be stained with the organisms *in situ*.—*Centralblatt für Bakteriologie, Parasitenkunde und Infectionskrankheiten.*

Sponge Eduction.—W. P. McIntosh describes sponge eduction for the production of healthy granulations in wounds. Sponge grafts for surface work and eduction sponges (nipple-shaped portions of sponge for filling up cavities and lost portions of the surface deeper than the skin surface) should be cleansed by soaking in equal parts hydrogen peroxide and saturated solution of boric acid. The sponge should be fine-grained and stiff, and should be cut transversely to the pores; the sections should be one-twentieth to one-sixteenth of an inch in thickness, should, of course, be perfectly sterile and, after being applied, be held in place by two strips of zinc oxide plaster and kept constantly wet with boracic-acid-hydrogen-peroxide solution by means of a medicine dropper, the patient being given the solution with directions to drop it on every few minutes. The sections of sponge should be put on so that the granulations can grow up into the tubes of the sponge. They must be changed every few days. There is no process equal to this method for changing an ugly depraved sore into a healthy granulating wound, for healing abscess cavities and for restoring lost finger tips to the extent of half an inch or more. There is no pus in these wounds. We can truthfully say that the wound heals by first intention.—*The Mobile Medical and Surgical Journal*, March, 1903.

On a New Method for the Application of Widal's Test for the Diagnosis of Typhoid Fever.—Arthur J. Wolff describes this method as follows: A loop from the fæces of the suspected case is smeared upon the surface of an agar slant in a prepared tube, and sent to the laboratory. From this one or more bouillon cultures are prepared. The bouillon must react from 1 to 2 per cent. alkaline with the $\frac{n}{01}$ acid, using phenolphthalein as the indicator. The infected bouillon is now incubated at the usual temperature for twelve hours, when the examination may be made. A sample of the blood is taken at the same time with the fæces. This is mixed with the bouillon culture and placed upon the stage of the microscope. If there is enough agglutinative material present, the typhoid bacilli, if they are there, will soon form clumps, which will be seen full of colon bacilli in active motion. If this reaction does occur, the case has advanced at least to the second week. If there is no reaction, another sample of the bouillon culture is tested with the blood from an advanced case of typhoid, whose agglutinative power has been tested by the ordinary method with a pure culture of Eberth's bacillus. In thirty-five tests of cases in the earlier stages, every case that gave a positive reaction turned out to be typhoid, while in a large number of other tests, from which no reaction was obtained, there was not one which gave even a doubtful reaction.—*The American Journal of the Medical Sciences*, April, 1903.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending May 16, 1903:

SMALLPOX—UNITED STATES.

			Cases	Deaths.

PRIMARY AND RECURRENT MAMMARY CARCINOMA TREATED BY THE *X*-RAY.

BY WILLIAM JAMES MORTON, M.D.,

NEW YORK.

PROFESSOR OF ELECTROTHERAPEUTICS AND OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

WHATEVER early expectations may have been, later experience has shown that the treatment of cancer by the *x*-ray is, in many instances, a long and difficult one. True, cases of the rodent ulcer type get well most rapidly; again instances of sarcoma and of recent recurrent nodules or of infiltrations in the scars of operations, disappear in a few weeks and also certain primary carcinomatous tumors of the breast disappear in a reasonable time. But the process of ascertaining the true limitations of the *x*-ray in cancer, in general, is a slow one. And to add to the difficulties of the problem there are those whose opinions are entitled to great confidence who claim that the high-frequency, high-potential electricity associated with a certain class of *x*-ray administrations, exercises, if not the whole, at least the preponderating influence toward the cure, when this is effected.

To arrive at an impartial view of what may be expected of the *x*-ray treatment, it would be essential to report all cases, both favorable and unfavorable, and this, so far as my own experience extends, I intend to do at an early date, but at the present moment I present a few cases in which the *x*-ray has relieved, or caused the evidences of disease to disappear and thus apparently cured. But although a doubt as to whether the *x*-ray itself or whether the high-potential, high-frequency current accomplishes the result may be said to be arising, still the fact itself is well established that cancerous disease, when not caused to disappear altogether exhibits, at least for a longer or shorter time, a retrogression under *x*-ray treatment. There are, however, exceptions even to this statement, for I have watched an advanced and inoperable carcinoma of the neck, and in another instance equally advanced and inoperable carcinomatous glands of the axilla steadily growing in size in spite of and in the face of most faithful treatment. And, again, in a case of extensive ulceration of recurrent and inoperable carcinoma I have observed recurrent cancer areas steadily disappear, while at the same time the case went on to a fatal termination, due to the existence of cachexia and of secondary septic infection. Or, again, I have caused local cancer to disappear and yet known death to ensue from distant and unexpected metastases. If then we would still claim that the *x*-ray is as nearly a cure for cancer as any other method of procedure yet found, we must also, at the same time, admit that from a comprehensive point of view it is certain that it is meeting with cases of certain stages and types which it cannot under present management and conditions overcome.

While all admit that the more superficial the growth, the greater are the chances of cure, be the case one of epithelioma, of primary or recurrent carcinoma or of sarcoma, my own experience furthermore leads me to believe that the newer the new growth is, the more certainly will the *x*-ray act favorably upon it. But as a modification to this view I would suggest that the more preponderant the "scirrhus" or fibrous character the slower is the action of the *x*-ray.

When an open ulcer with much secondary septic infection exists, the case is almost sure to progress unfavorably.

There is also reason to believe that the connective tissue stroma in some cases of scirrhus is caused to grow, while at the same time the cancer cells degenerate and decrease. Much time, therefore, will yet be required before we may differentiate what cases of cancer may be successfully combated by the *x*-ray, and until we can decide what the limitations as to treatment are. In the meantime, looking the field over—taking conservatively into account both successes and failures in my own as in the reported result of others—I think there is ground for the belief that in the *x*-ray we possess a relief or cure for cancer, especially in its early stages, which in its ultimate results compares favorably with operative treatment. It would seem to me that a case of primary carcinoma of the breast may as hopefully, and with as little ultimate danger to the patient, be submitted to the *x*-ray as to any other procedure. I believe that properly selected cases of primary mammary carcinoma or other cancer may be submitted to the *x*-ray before resorting to an operation with a certainty that no valuable time will be lost. For if the *x*-ray does not succeed in effecting a cure, the patient is at least in a better condition for operation than before, for the reason that the outlying areas of infection are cleared up and the actual remaining disease is more accurately localized to a given and known position.

It is now pretty generally accepted that the *x*-ray should be employed after an operation in order to prevent a recurrence. It may reasonably be asked if the *x*-ray is effective to prevent a recurrence or to cause a recurrence to disappear, why is it not equally effective in the first instance and before an operation. I trust that some of the cases I here report may help substantiate this view.

I am fully aware of what it means to advise a patient with a primary carcinoma of the breast or elsewhere to delay operation. Could the operation positively preclude a recurrence or, again, could the *x*-ray present a certainty of cure, there could, of course, be no hesitation as to the advice to give. With wider experience before us, as to the capabilities of the *x*-ray the time of doubt should soon be over, and at the present moment there exists no other course than frankly to lay before the patient or the patient's family "the present state of the art" of *x*-ray therapy and of surgery, and if the *x*-ray course is chosen, to follow it only so

long as the patient makes decided progress toward recovery. If no progress is made, an operation, if one were ever possible, may still be done and the *x*-ray continued later on. At this point some one will remark, "but valuable time will be lost." This I do not believe. For in breast cases I have observed that infected, indurated, swollen, and sensitive lymphatic vessels and lymph glands have become, to all intents and purposes, normal, even though, in several instances, I have thought it wise to have a rebellious (to the *x*-ray) scirrhous lump removed finally by the knife.

I may say here in general that one class of cases which all have found to be the most resistant to *x*-ray treatment and altogether incurable by its aid is precisely that class of cases which have advanced to a stage where no surgical operation is possible. On the other hand the *x*-ray has already cured some of these inoperable cases.

One fact at least stands forth most clearly, and that is that cancerous disease in its incipiency, when not too deeply located, is decisively arrested in its growth and caused to disappear.

Case I.—Miss L. M., aged forty-five years. Diagnosis: Primary carcinoma of breast. Referred to me by Dr. Wm. F. Fluhrer, May 11, 1902.

In view of the extreme interest attached to the outcome of this class of cases I quote from Dr. Fluhrer as follows: "May 5, 1902. Dr. Wm. J. Morton, Dear Doctor: If you continue to think favorably of the curative power of the Röntgen rays in the treatment of cancer, I would like to refer to you for treatment a patient with scirrhus of the breast, early stage. I was about to appoint a day for a radical operation, but . . . published results dispose me to make a trial of the *x*-rays, especially as my experience has made me very pessimistic concerning the ultimate outcome of all operative procedures in these cases." In accordance with the above expressed intention to operate, the patient had already engaged a room at a hospital in this city.

History: A sister died of cancer.

The patient first noticed a tumor in the left breast three months ago. A bunch of external lymphatics running toward the axilla were sore to the touch and enlarged. There is an enlargement of a gland in the axilla and a "steady, aching pain in the left arm."

The actual tumor measures $2\frac{3}{8}$ by $2\frac{6}{8}$ inches, measurement of normal gland at the same point on the right breast $1\frac{3}{8}$ by $1\frac{6}{8}$ inches.

Treatment *x*-ray, high tube, three times weekly, 9 inches distance from target.

May 23: Seventh treatment. Tumor smaller and mass feels harder. The soreness in the lymphatic areas has continued until to-day when it, at least for the time being, has entirely disappeared, also the pain and discomfort of the arm has disappeared.

May 26: Soreness on pressure on inner side of breast remains absent, but on outer side again present. Tumor feels harder.

June 11: X-ray dermatitis to the extent of exfoliation of the epidermis and serous effusion established. Nipple and areola quite sore. Soreness and pain within breast long since entirely ceased.

June 16: Dermatitis subsiding, but skin quite sore and purple red, and areas of exfoliation and serous effusion exist. The dermatitis involves the entire breast and chest above the breast up to the chin and the entire axilla. This dermatitis could not have been carried a step further without danger. The patient was now *x*-rayed from behind.

Dr. Fluhrer examined the tumor and reports that, according to his judgment, it is reduced one-third in size.

June 27: No dermatitis. The skin appears clean white and new and all scales have rubbed off.

No evidence of tumor can be discovered, but the tumor region is still sensitive to pressure.

August 16: Measurement of tumor mass $1\frac{3}{8}$ by $1\frac{6}{8}$ inches; namely, the same as the corresponding mass in the right breast. No lymphatic channels or glands are enlarged, sore, tender or painful, and it is recorded that the case "looks very hopeful."

October 22: During the summer, treatments were given only twice weekly, and might possibly have been discontinued altogether in August, had I not believed it unwise to accept the evidences of disappearance of the disease as apparently final.

The patient was now again examined by Dr. Fluhrer, who stated there apparently was no tumor or trouble remaining. I thought wise to continue treatment once a week however.

November 2: The disappearance of the disease was again confirmed by Dr. Fluhrer who also referred her to Dr. Chas. Putnam, who agreed in the report.

Treatments are now discontinued and patient is well to date.

Total number of treatments to November 2, seventy-four, extending over a period of about six months. Disease, however, probably at an end so far as can now be known at end of August, three months, with twenty-five treatments.

I append in present conclusion of this case a letter from Dr. Fluhrer confirming the result thus far attained. I have previously in another publication referred to the fact that the breast treated by the *x*-ray is inevitably developed and becomes larger and firmer as referred to below:

"My Dear Dr. Morton: I have this morning carefully examined Miss M. The formerly affected breast is slightly larger and slightly firmer in texture than the other breast. There is no evidence whatever of the tumor in the breast which was previously present. The lymphatics along the edge of the pectoral muscle are no longer thickened. The glands in both axillæ can be felt. On the side of the formerly diseased breast they are very slightly more perceptible, but appear to have the normal softness of texture on both sides. The patient presents no evidence of cancer.

Case II.—May 5, 1902: Miss V. R., aged twenty-five years. Ulcerated primary carcinoma of right breast, far advanced. Referred to me by Dr. B. Onuf with the above diagnosis; clinical diagnosis also confirmed by others. Disease began two years ago, two weeks subsequently to a trauma. She had received an accidental blow upon the breast, followed about two weeks later on by a second one on the same spot. First noticed a hard lump on the outer and lower aspect of the breast. This lump steadily grew larger and now measures $2\frac{3}{4}$ by $2\frac{1}{2}$ inches in diameter, extending deeply into the breast; it is firmly adherent below to the fascia and causes extensive retraction of the tissue. Extending from the tumor toward the axilla is located a further and continuing mass of indurated tissue, three inches long and one inch in diameter, evidentally corresponding to infected lymphatic vessels. The axillary glands are involved to a great extent, some of them being agglutinated into a large mass; they cause her much pain, and are sore upon pressure. A discharging ulcer, the size of a silver dollar, exists at the site of the initial tumor and a discharging fissure at the nipple. The right arm is painful and much swollen with brawny œdema. Pain involves

the entire shoulder. She suffers sharp pain, generally at night, and loses sleep. Has lost thirty pounds in weight during the last year. Has concealed the existence of the disease by reason of modesty and fear of an operation.

Treatment.—*X*-ray, high tube, three times weekly, fifteen minutes usual technique.

May 21: Treatment gives relief from pain for at least twenty-four hours—in fact, has now very little pain either in breast or in axilla.

June 4: Severe dermatitis with serous effusion and exfoliation of epidermis.

June 16: Dermatitis disappeared and skin again sound. Feels more comfortable than for a long time. Main masses smaller and uses arm without fatigue.

August 8: A succession of attacks of dermatitis with subsequent desquamation had been set up. The ulcer has now entirely healed, and the initial tumor beneath it has disappeared. The mass corresponding to the infected lymphatic vessels is very much smaller, but still persists, as well as a small gland in the axilla. Sound normal skin, loose and flexible, covers the seat of the disease. The patient appears to be in excellent health, has a good color and good appetite, and suffers no pain anywhere. The œdema of the arm and hand has entirely disappeared and the patient has perfect use of the arm and without pain.

Treatment continued in November and December as usual.

Duration of treatment to December 6 is seven months. The number of treatments 93.

We have here a case of neglected primary carcinoma of the breast advanced to the stage of ulceration and profoundly involving lymphatics and lymphatic glands, and which shows most conclusively the healing effect of the *x*-ray.

Case III.—Mrs. E. P., aged seventy years. Diagnosis: Primary carcinoma of the breast.

May 14, 1902: Last August first noticed a small tumor on the outer and under side of the right breast. This tumor has grown steadily in size until it is now the size of a large goose egg, but with no especial pain. The nipple is retracted, and also there is a deep retraction of the skin over the central portion of the tumor. The tumor is of the scirrhous type; the entire mammary gland is apparently involved, and the tumor is rigidly adherent at its base, appearing to be attached firmly to the ribs. There are glandular enlargements in the right axilla. The patient has firmly declined an operation, saying she will die with her tumor rather than have the breast and surrounding tissue removed.

X-ray treatment, three times weekly, begun.

In about one month the tumor had reduced in size in a very marked degree, and now took on a longer and narrower shape, detaching itself out, as it were, from the remainder of the breast. By the end of the second month the tumor was scarcely the size of a small hen's egg, was freely movable as regards the attachment to the ribs or rib, but some retraction of skin still remained. The attached nipple and areolar region was now also freed and no enlarged glands in the axilla could be felt. At the end of the third month (forty-six treatments) only an extremely hard mass about one and one-half inches in length by one inch in width remains. This mass is freely movable, but retains some adherence to the skin immediately over it. It could be surgically removed by a very simple enucleation from its surroundings, and this I advised as the shortest way out of her trouble. The patient took this view into consideration. It is my opinion in this and in similar cases that the cancerous and malignant nature of the new growth has disappeared, and that only a connective tissue stroma remains, which it may be impossible to cause to disappear by the *x*-ray.

December 4: The patient has taken desultory treatments during September, October, and November, amounting to fifteen in number, and presents to-day about the appearance above described, except that the remaining hard and slowly reducible nucleus is still smaller. The patient refuses even the minor operation above proposed.

January 2, 1903: Dermatitis well established with serous effusion over the remaining tumor, which is now about the size of a walnut. Have desisted from treatment to await further absorption.

Case IV.—Mrs. L., aged seventy years. Diagnosis: Primary carcinoma between left breast and axilla.

March 24, 1902: Last summer patient first noticed a small kernel which has steadily grown to its present size. Examination now shows a flattish tumor six inches in diameter the central portion of which consists of a very hard disk-like mass measuring three inches across with irregular nodular edges and retraction and involvement and attachment of the skin to the tumor at the center. Most of the tumor was adherent at its base. The central portions of the skin were retracted, forming a saucer-like depression. The growth was sensitive to pressure and subject to "twinges" of pain. Patient has refused to submit to any operation.

Treatment.—*X*-ray, three times weekly, fifteen minutes, technique as described.

At the end of a month all of the comparatively soft and outlying parts of the tumor around the central hard mass had entirely disappeared, while at the same time the central hard portion had reduced one-half an inch in diameter. All pain and soreness had also ceased.

No shield was employed, and the axilla, side and front of the chest soon became intensely brown. From this point on there was nothing to observe except the steady but slow diminution in size of the central scirrhous mass, originally measuring, on October 8, three inches in diameter. After a fairly continuous treatment of six months this central mass still measured two inches in diameter and was much thinner from its surface to its base. It had also become detached at its base and was consequently now movable. The retracted center had flattened out. It was now evident that the greater part of the patient's disease had disappeared, and that she was free from danger of its spreading, but also evident that the remaining nucleus yielded, while surely, it is true, still slowly.

The patient felt her age, and was feeble, and the journey to come for treatment was for her a long one. She had reached a stage where the remaining nucleus could be simply removed without resort to the extensive operation involving other areas which otherwise would have been deemed necessary. For the *x*-ray had already removed more than two-thirds of the mass and with equal certainty, if there ever was an inferential certainty, cleared up all involvement of surrounding lymphatics.

In November, without my knowledge, the patient was operated on by Dr. J. W. Wright of Bridgeport, Conn. Unfortunately, the tumor, by an inadvertence, was thrown away without microscopical examination. Dr. Wright, in a letter to me, states that the tumor was a carcinoma and, microscopically, seemed to be degenerated in spots. My feeling in this case, as in other similar ones, is that a primary carcinoma like this one

should be *x*-rayed firstly and operated upon lastly, if necessary, thus substituting a minor and unimportant surgical operation for what is acknowledged to be a most severe one, and, what is more probable, offering a greater security to the patient against a recurrence than the grave primary operation.

Some weeks after the operation the patient died from exhaustion of old age and intercurrent conditions, but it does not appear that her death was due to cancer.

Case V.—Mrs. M. E. H., aged forty-five years. September 9, 1902—Diagnosis: Primary carcinoma of breast.

Eight years ago had both ovaries removed for ovarian tumor and one year later the uterus was removed for malignant disease. Soon after the second operation she noticed a tumor in the right axilla, which for the last two years has pained her excessively. For the last six weeks she has noticed a fulness and soreness in the right breast, and a sensitive tender ridge-like swelling extending from near the nipple toward the axilla. The breast gives considerable pain. On examination a small tumor is felt on the outer aspect of the breast, attached to the gland, and running from it the sensitive chain of lymphatic vessels alluded to. The enlargement of the lymphatics was about as large and as long as one's little finger. The tumor in the axilla would seem to be a fatty tumor, and the patient was so advised, but the other tumor and the lymphatics were treated by the *x*-rays.

October 20: Patient has received about nine treatments. Severe dermatitis established. The painful ridge of lymphatics has resolved to two small lumps, each still quite sore to pressure. The sense of "fulness" of the breast and the pain have altogether disappeared. The tumor of the breast no longer exists.

Since the dermatitis was still quite severe, the patient refrained from treatment, and on returning three weeks later reports no further trouble remaining. On examination one breast appears to be as normal as the other. Disease entirely disappeared.

Case VI.—October 1, 1902: Mrs. H. J., aged forty-five years. Diagnosis: Primary carcinoma of breast. Referred by Dr. J. McCroskery. Upper margin of the mammary gland of the right breast, the seat of a hard tumor adherent to gland tissue, and measuring, inclusive of the gland at a given level, $2\frac{1}{4}$ inches as compared with a similar measurement at the same level of the left breast, of $1\frac{3}{4}$ inches. Lymphatic vessels sensitive and enlarged and an enlarged gland in the axilla. On the under side of the breast and in the skin exists a kernel as large as a pea.

Patient suffered pain quite steadily and has been losing flesh.

Treatment *x*-ray; usual technique.

October 14: Soreness of lymphatics and tenderness on pressure over tumor and spontaneous pain have disappeared.

November 20: Measurement of tumor slightly less than two inches across. The kernel in the skin has entirely disappeared and the enlarged gland in the axilla has disappeared.

December 2: Patient has gained six pounds during the last month.

December 13: No pain. No tumor or enlarged glands can be found. Patient referred back to Dr. McCroskery, who reports that he can find no tumors and wholly confirms the disappearance. Dermatitis with serous effusion and exfoliation of the epidermis was produced three times during treatment.

Duration of treatment ten weeks, and total number of treatments, thirty-three.

January 31, 1903: No sign of disease. The gland measurements are identical. The breast treated is, however, somewhat larger and firmer than the other breast, as is usual as a result of the *x*-ray treatment in these cases.

Case VII.—Mrs. A. A. N., aged thirty-five years. November 6, 1902. Diagnosis: Primary carcinoma of breast.

First noticed one year ago a small lump about as large as the end of her thumb in the right breast, outer and lower aspect. This grew slowly until two months ago it began to get larger and now is the seat of "crawling" and, at times, stinging pains. Examination reveals a hard, nodular tumor, attached to the gland and forming a part of it, one inch in diameter, and, extending toward the axilla from the tumor, a lengthened, elongated, sensitive mass, evidently affected lymphatic vessels, measuring two inches in length. Glands of the axilla are quite sensitive.

Treatment.—*X*-ray, high tube, corresponding to a nine-inch mark, fifteen minutes three times weekly. No shield. Breast, axilla, and thorax fully *x*-rayed.

December 9: Pain ceased after the second treatment. The elongated lymphatic mass has entirely disappeared, thus bringing into prominence day by day the individual hard tumor, which itself has now almost disappeared. Axillary glands no longer sensitive. Dermatitis with itching and burning well established.

December 16: Dermatitis subsiding. The epidermis is peeling off in large flakes, as in the case of a sun blister.

The tumor can now only be found with difficulty, and consists simply of a small hard kernel.

January 7: Careful examination to-day with patient in recumbent position, reveals no sign whatever of the previous tumor, or of the lymphatic enlargements. Patient's treatments reduced to twice weekly for the present.

Owing to the full development of the right breast, namely increase in firmness, hardness, and roundness, it is necessary to administer *x*-ray to the left breast to even up the symmetry of the bust.

February 20: Patient remains well and is treated merely to make sure of the present result.

Case VIII.—Mrs. M. L. D., aged forty-eight years. Diagnosis: Primary carcinoma of breast.

December 6, 1902: First noticed two days ago a hard tumor in the breast about the size of a walnut. No pain. Consulted Dr. W. H. P. Pratt of Brooklyn, who kindly referred her to me.

Examination.—Tumor, left outer aspect of left breast, measuring two inches by two inches in diameter, very hard, surface not smooth but nodulated, apparently movable only as a part of the mammary gland and apparently becoming fast to the skin. Complains that her clothing pinches the shoulder, and there is evidently tenderness in the axilla.

December 18: It is very remarkable to observe how rapidly the tumor is diminishing in size. It now measures scarcely one inch in diameter. She still complains of tension in the shoulder and arm.

January 8, 1903: This morning appears for the first time an *x*-ray rash in the shape of small papules not yet confluent.

January 15: Severe dermatitis has followed since last record, but is now subsiding, except for a spot denuded of epidermis just over the tumor.

Referred back to Dr. Pratt, who reported that the case was a "transformation scene," that he could not have believed that such a tumor could

have thus far disappeared except on the evidence acquired by his own fingers. The main bulk of the tumor has disappeared, which is all that and more than could be expected in the short time of one month. A small kernel undoubtedly remains and treatment is continued.

April 1: Left breast firm, hard, and larger than right. Absolutely no sign of a tumor can be discovered and the patient is apparently cured.

Case IX.—Mrs. C. M., aged sixty-two years. Diagnosis: Primary carcinoma of the breast.

November 3, 1902: Kindly referred to me by Dr. Fuhs of Brooklyn as "a tumor which should be removed by surgical operation." This opinion was confirmed by Dr. Rushmore of Brooklyn. In August noticed a retraction of the skin forming a considerable depression of the contour of the breast, and soon noticed a second retraction near to the first one. These depressions are much increased on raising her arm above the head. October 28 noticed a "lump" near the retractions and nearly beneath them. No pain or soreness on pressure. Has lost seven pounds in weight.

Examination.—Tumor situated on the inner aspect of the breast, measuring 1½ inches in length by ¾ of an inch in breadth, nodulated, hard, attached to gland at its base. Enlarged gland in axilla.

Treatment.—*X*-ray.

November 17: Tumor somewhat smaller and harder and more defined.

December 1: Tumor reduced to one inch in length.

December 22: Tumor decidedly less than one inch in length. Dermatitis fully established. No sensitive glands in axilla.

January 5, 1903: Tumor, say, ½ inch in length and very hard to palpation. Retractions still persist but are less marked.

February 10, 1903: No sign of the disease can be found, except possibly a small remaining kernel and some retraction of the skin, forming a depression like a dimple.

This tumor was undoubtedly of the fibrous or scirrhous type and yielded slowly, and may be possibly yet far from total disappearance. As in case 18, treatment must be continued, but reasoning by anology with other cases, all signs of disease will finally disappear.

Case X.—August 20, 1902: Mrs. J. L. S. Diagnosis: Recurrent carcinoma ,of one breast and a primary carcinoma in the other breast.

Disease began two and one half years ago. Patient first noticed an intense itching and prickling, as of needles, in and about the left nipple. In about six months a small lump appeared near the nipple. She consulted her family physician, who told her she was "hipped," and to go home and disregard the lump. In the following Spring she consulted him again, since her symptoms persisted, and he decided to "take it right out." The operation was performed by removing the entire nipple and areola and deeper adjacent tissues. The removed specimen was sent to two pathologists, who made the following reports, which I quote somewhat in full because of their important bearing:

College of Physicians and Surgeons, Columbia University, Department of Pathology. Mrs. J. L. S. New York, May 14, 1901: The tumor of the nipple presents rather unusual morphological features, some parts of it considerably resembling endothelioma. But a careful study of it leads me to the diagnosis of adenocarcinoma.

From the operative standpoint, the tumor should, in my opinion, be considered carcinoma.

Mrs. J. L. S. New York City, May 7, 1901: Specimen of tissue from nipple. First examination: Specimen hardened in paraffin, cut and stained forty-eight hours. Four sections examined. Diagnosis: Adenocarcinoma.

Second examinotion: Specimen hardened in celloiden, cut and stained one week. Five sections form various levels examined. Diagnosis: (final) Adenocarcinoma. C. N. B. Carnac, M.D.

Examination, Left Breast.—No nipple or areola. Linear scar, 1½ inches in length, remains from removal of the tumor at this point. In each of the three stitch-marks of this scar is situated a small, red, hard tumor, somewhat smaller than a pea in size. From the central tumor there extends downward an area of red and hard skin infiltration about the size of the thumb nail. The patient's chief anxiety is caused by a very sore and tender spot in the upper and outer quadrant of the breast. Palpation develops pain and a hard, corded, and sensitive mass of lymphatic vessels at this point. There are also sensitive glands in the axilla.

Right Breast.—Exactly the same condition exists in this breast as is above described to have begun two and one-half years ago in the left breast, namely, a small, red, itching, hard kernel near the nipple. The nipple also is indurated and fissured as formerly on the left side. A lymphatic tenderness and swelling also exists in this breast at the same site as in the other. In this state of affairs, and recalling the pathological reports quoted, few would deny that the classical advice would be the complete removal of both breasts and the clearing out of both axillæ, if indeed, an operation would be advised at all.

It is well recognized that even a small carcinomatous tumor of the breast may quite early establish an involvement of the near lymphatics and a general infection along the line of the pectoral muscles, and within the axillæ, and in the case now under consideration such infection had evidently occurred on both sides. The tumors and the course of the spreading disease bore no resemblance to the course of a latent scirrhus of a local type. All surgically operative interference had been refused by the patient and certainly the case should prove to be a severe test of the efficacy of the *x*-ray.

It is by reason of just such cases as this one that I long ago advised that no shields for the thorax ever be used.

Treatment.—*X*-ray, three times weekly.

October 8: An extensive dermatitis of the breast and axillæ has now existed for some weeks The epidermis has exfoliated over an area of about four inches in diameter, and serous effusion is taking place. The pain in the lymphatic swellings of both breasts is much less, but the areas still feel hard and cord-like and are sensitive. The interesting point developed is that the cancer infiltration of the skin, of the size of a thumb nail, has entirely disappeared, as well also as two of the three small tumors. The small central tumor still remains.

At this time the general infection of the thorax on both sides was so marked and widespread that (considering also the appearance of the disease in the second breast) I took into account an abdominal tumor complained of by the patient, and referred her to Dr. Bache McE. Emmet for diagnosis of this tumor. My fear was that it might be cancerous, or, at least, be breaking down and furnishing septic material. Dr. Emmet pronounced the abdominal tumor to be an inert and harmless fibroid.

October 22: Treatment continued since October

3 three times weekly. Dermatitis of left breast area entirely healed. No pain now, on pressure on the lymphatics. The one remaining kernel feels like a small grain of sand.

November 17: No signs whatever of trouble can now be discovered in the left, the originally affected breast. But the right breast is still short of recovery since the lymphatics are sensitive and "knotted," the nipple is still somewhat hard and the small kernel persists.

December 6: Right breast now apparently all right except for the persistent kernel. To attack this kernel a small hole is cut in a lead shield and a violent *x*-ray projected upon the tumor.

January 31: Patient leaves for the South at my advice, since her disease is now apparently cured, but she is advised to return at once upon the reappearance of any of her easily recognized symptoms.

Of course, this case must be kept under general observation for some time to come, but the outcome would seem to indicate that small carcinomatous tumors of a highly infectious type may be effectively controlled in their progress and that the infected areas also may be cleared of the infecting cancer particles.

Duration of treatment about five months, and number of treatments sixty-five.

Case XIX.—Mrs. M. T., aged forty years; married. Carcinoma mammæ, recurrent.

November 21, 1902: Four years ago (last January) a small tumor as large as a chestnut appeared in the left breast. In March immediately following it was operated upon in the Hospital Jesu Maria in Naples, Italy. In March, 1902, the first recurrence was noted, and on October 6 the breast and glands of the axillæ were removed at the Columbus Hospital, and the diagnosis of carcinoma made microscopically. To-day, about six weeks later on, there exists a second recurrence in the shape of a nodule, in diameter about the size of a thumb, and situated in the skin of the chest, just below the axilla, and quite independent of the cicatrix. There exists also a considerable infiltration and consequent thickening of tissue at the edge of the pectoral fold near the upper limit of the cicatrix. At the latter situation, she suffers much pain, extending down to the arm and up to the occiput and throughout the shoulder. No pain in the nodule.

Treatment.—*X*-ray, usual technique, three times weekly, fifteen minutes each treatment.

November 28: Pain has abated.

December 3: Still some pain, but recurrences are diminishing in size.

December 15: Induration near upper end of cicatrix is very soft and flexible and has almost disappeared.

Now, at the end of twenty-four days and with seven treatments, the recurrent nodule has entirely disappeared. It first flattened out gradually, next left an indurated and firm base, and now its site is recognizable only by a reddish, deeply pigmented fleck or spot.

There is no fact better established in the *x*-ray therapy of cancer than this rapid and positive disappearance of recent carcinomatous nodules in the skin. I have seen groups of six to fifty such recurrent nodules fade away at the end of less than a month, leaving an apparently normal skin behind. No one will deny that in such instances the *x*-ray favorably displaces an operation, while all must admit that the fact distinctly indicates that recent carcinoma is the most susceptible to the *x*-radiation.

Case XX.—Mrs. D. M., aged thirty-six years. Recurrent carcinoma of breasts and axilla.

August 27, 1902: Patient referred to me by Dr. John McCroskery of New York City. In 1885 noticed a tumor in the left breast. In 1887 this tumor was removed by Dr. Bedell of Lamar, Col., and the patient reports that the "tumor looked like a chicken gizzard covered with warts." Microscopical examination proved it to be a carcinoma. Soon the disease extended over the outer side of the breast and up to and into the axilla, and the arm began to cause her intense and continuous suffering. The hand "goes to sleep" if the arm is allowed to press against the body.

Examination.—Left breast, three tumor masses of about one inch each in diameter, also an indurated, enlongated tumor, representing the infected lymphatics, along and beneath the pectoral folds, and also one especially large gland the size of an English walnut in the axilla, as well as the other sensitive and enlarged glands at the same locality. In the right breast exists also a small tumor. The left arm is enlarged.

The patient suffered intense pain and had got into a highly demoralized and nervous condition, owing to the necessary use of morphine and alcoholic stimulants, to relieve the excessive suffering. She exhibited a most pronounced appearance of carcinosis—her color was "yellowish green" and had been so for about three and one-half years. The case seemed most unpromising for *x*-ray or any other treatment.

December 8: Patient has come for treatment very irregularly, but the results may be summed up as follows:

About November 8 extensive dermatitis had been established, and the patient, on this account, had remained absent a month, though I should have preferred to have gone on with the treatment. She reports that the dermatitis was very severe, that it extended over the under surface of the left arm and over the skin of the axilla and over the entire left breast, and even over the abdomen as far as the groin. On the breast at present is a large blistered surface with blisters full of yellowish serum.

But as a result of the treatment the patient is in a much better condition than for years. She has recovered her appetite and ceased her attacks of vomiting. Her yellowish green color has yielded place to a natural and healthy color. She has been able to cease entirely the use of large doses of morphine, and requires no alcoholic stimulants. She has regained full use of the left arm, and has no longer numbness nor pain nor swelling in the arm or hand. She has no pain in the breast and, most essential of all, the three tumors have entirely disappeared, the mass at the pectoral fold has disappeared, though at that point a sensitive spot remains. The glands in the axilla cannot now be felt.

This case I submit as one of many I might bring forward in which the *x*-ray has produced a very decided retrogression in the progress of carcinoma and carcinomatous infection. The patient now went West on a visit, and I have no further knowledge at this date as to her condition, though Dr. McCroskery writes me that at his last examination the patient retained her improved condition.

Comments on Cases of Primary Mammary Carcinoma.—No shields, except for the hair of the head and eyes, are used, and except that the nipple is covered with a small metallic disk during about two-thirds of the treatment. Dermatitis is intentionally carried to a red purplish stage, followed by exfoliation of the epidermis and effusion of serum, and in certain cases purulent effusion, but

in all but one case a complete restoration of the epidermis to its normal type has followed in from one to four weeks. These areas of dermatitis have often occupied the entire skin area of one breast and axilla. The patients are frequently *x*-rayed from behind the scapula, the fluoroscope showing that the thoracic cavity offers but small obstruction to the radiation. This measure seems to me very important in view of the researches of Volkman and Heidenheim, who have pointed out that, even in the case of a very small carcinomatous nodule the deep fasciæ of the muscles of the chest may be infected. Or, again, the anterior portion of the ribs and the clavicle may only too effectively shield infected areas behind these bones. I do not hope for good results in these cases except by the production of a severe and extensive dermatitis. Fortunately, I have not overstepped bounds and reached a necrosis, and if I have escaped this it has only been by adhering to the most rigid and exact technique as to time of exposure, distance of tube, force of radiation, and number of treatments per week. This technique, I may mention, is fifteen minutes, nine inches, "high" tube (corresponding to six to ten inches spark gap), clear view of end of radius and ulnar at two feet, and three times weekly. An inexact technique would surely lead to a too severe burn, and I am not sure but that an exact one will sometimes do the same. Thus far I have escaped producing this unfortunate result.

As to the exactness of the diagnosis of carcinoma in the cases reported, one must exercise their own judgment. It is, of course, impossible to excise a piece of the tumor for preliminary diagnostic purposes. But accepting the opinions of competent observers, the margin of error as regards malignancy is a fairly small one. Dr. George F. Shrady (MEDICAL RECORD, January 26, 1901), in arguing for an accurate early diagnosis, and in favoring an exploratory examination of every tumor before its actual extirpation, says: "Mammary growths, as a class, can never be trusted. The weight of evidence is so strongly on the side of malignancy, threatened or pronounced, that no conscientious practitioner can afford to have any doubts as to the responsibilities he should assume. There is hardly a 'simple tumor' in the breast which may not become malignant. Fully 90 per cent. of breast tumors in older women are probably malignant, and the remaining 10 per cent. are very objectionable tenants." Again C. V. Visher (*American Medicine*, August 24, 1901), arguing that "the success of operative intervention depends so much on its early performance that the question of diagnosis becomes second only in importance to that of the treatment," goes on to say, "It is true that not all neoplasms of the mammary glands are carcinomatous, but when it is borne in mind that 80 per cent. of breast tumors are of this nature, and of the remainder 4 per cent. are sarcomatous, and the balance, 16 per cent., consists of the more innocent growths, which include adenoma, and as these growths commonly undergo malignant changes, the opportunity for a mistaken diagnosis is slight, and the benefit of any doubt should always be conceded to the patient. How much safer would it be even to remove one breast for a benign tumor than to permit eight malignant growths to remain, and finally cause a fatal termination."

The "American Text-book of Surgery" gives 83 per cent. of tumors of the breast as carcinoma, and if 4 per cent. are sarcoma, then we have 87 per cent. as malignant from the start. If to this we add, say, 6 per cent., probably a low estimate, for the adenomata that become malignant, we have 93 per cent. of tumors of the breast that are or become malignant. I do not in the least contend that the cases I have here reported are in any sense conclusive as to the propriety of treating primary carcinoma of the breast by *x*-ray rather than by operation. Far from it. Such cases are merely preliminary and tentative. Had they lost ground at any moment I should have advised operation, even with the certainties of recurrence. I have one case of primary carcinoma of the breast in which a diagnosis has been made by incision and removal of a section, which has now been under treatment seven months, and which, though greatly reduced in size, still persists. I have known of another case treated thoroughly for the same length of time by the *x*-ray with but little benefit, in which the tumor has just been removed and proved by microscopal examination to be carcinoma. Both cases were of the hard fibrous type. Therefore I feel sure that the whole subject is yet *sub judice* and merely offer some of my results as a contribution to the general whole. But I also feel sure that some cases of primary carcinomatous tumors disappear.

And here, lest I may be misunderstood in regard to producing as above described a *severe* dermatitis, I would add that nothing would be more unwise than to do this in an ulcerating carcinoma, for the carcinomatous infection will almost surely extend along the areas of the *x*-ray burn, and the disease become worse than if no *x*-ray treatment had been employed.

What is desired would seem to be to set up a mild leucocytosis with tissue reparation, and if in the case of a mammary and unbroken cancer the skin intervenes, this latter suffers a dermatitis lesion, merely to enable the operator to set up a similar but lesser lesion of the deeper tumor area. In this connection I have often observed, in cases of primary carcinoma, that at a moment when the patient complains of the soreness of skin due to a severe dermatitis she also remarks that the tumor itself is unusually sensitive to pressure. But in a superficial or ulcerating carcinoma or superficial recurrent carcinoma of the skin a milder treatment with no dermatitis of note will set up (granting the correctness of the leucocytosis theory) leucocytosis and reparation. To resume, I do not believe that any dermatitis or outside *x*-ray burning effect should be set up in ulcerating carcinoma or sarcoma, while, on the contrary, this must be set up in the case of deeper and non-ulcerating carcinomas and sarcomas in order to submit them to a requisite intensity of radiation and secure tissue repair.

In conclusion, as regards both primary and recurrent carcinoma and other forms of malignant disease, it obviously would not be wise to try to do with the *x*-ray what might be better done by the actual or other cautery or by the knife, and the best future for *x*-ray and phototherapy in general should be one of extreme conservatism and desistance from the invasion of surgical procedures which offer an alternative of relief or cure to the patient superior to what the radiation treatment can offer.

19 EAST TWENTY-EIGHTH STREET.

Women Inspectors Dropped.—Commissioner of Immigration Williams has received from the Secretary of the Treasury the following instructions: "You will issue to the women inspectors of immigrants the following notice: 'Your name not appearing on the eligible list of the Civil-service Commission, you cannot be reëmployed without executive order. No such order having been made and your term of service having expired under your temporary appointment, such services are hereby discontinued.'

THE TREATMENT OF PURULENT CONJUNCTIVITIS.*

By EDGAR S. THOMSON, M.D.,
NEW YORK.

My purpose in presenting to you this brief paper is not to discuss the well-known treatment of this disease, but rather to dwell upon some of the newer methods which seem to be establishing themselves permanently. The first step in the treatment of every case of purulent conjunctivitis should be the microscopical examination of the pus, by slide examinations, or by cultures, if necessary, so as to ascertain the variety of the microorganism present. Treatment need not, and should not, be delayed on this account, as in many instances every hour is of moment; but certainly no case can be intelligently treated without this information.

In cases that have the clinical appearance of gonorrhœa strong germicides should be at once applied, while in cases of less severity, and presumably caused by less virulent pus germs, it would certainly be a mistake to make the same application. In fact, the selection of the germicide is a matter of no little tact. Many effective germicides cause a certain amount of traumatism to the conjunctiva, although in some recent preparations this is reduced to a minimum, and we must consider carefully whether the effect we wish to gain is worth this disadvantage.

The gonococcus is the most virulent germ we have to deal with in the eye, leaving aside the rarely occurring diphtheria bacillus, and the clinical picture is apt to be suggestive. Almost every one is familiar with the brawny, swollen lids, the chemosis, the profuse, thick discharge of creamy pus—all coming on with great rapidity after infection, whether occurring in the adult form, or in the modified form in the newly-born infant. The disease varies somewhat, but in the great majority of cases is considerably more severe than the worst cases caused by other infections. In fact, I have come to doubt the existence of the so-called "mild cases" of gonorrhœal conjunctivitis, after the examination of a large number of cases occurring in the contagious wards of the Manhattan Eye and Ear Hospital during the last five years, as well as those occurring in my own private practice.

It is reasoned by many that we should find mild infections in the eye as well as in the genital tract, but the clinical fact remains that in mild cases of conjunctivitis we do not find the gonococcus. Such cases are often called gonorrhœal on insufficient evidence. Indeed, it is too often supposed that the eye condition is gonorrhœal without any examination of the pus. In gonorrhœal cases the treatment should be first of all directed to the destruction of the gonococcus, and our best means to this end is by the application of nitrate of silver. None of the new germicides seems capable of replacing silver entirely, and they are of use chiefly in cases in which silver is not well borne. It is imperative in adult cases that the application should be made at the earliest possible period after the infection. As soon as we see a case, a slide examination should be made and silver applied, as on this point often depends the success or failure of the case. If the gonococci once have a chance to penetrate the conjunctival tissue thoroughly, the eye will probably be lost, as it is impossible to reach them by germicides, and the process goes on until the cornea ulcerates. In babies, the results of delay are not apt to be so serious, as the cases are more manageable, but in every case the silver should be applied as early as possible.

When we see the case before the lids are much swollen—a period of a few hours in adult cases—it is sufficient to apply a two-per-cent. solution. This should be done by a swab of cotton on applicator. The eye should be cleansed, and the applicator carried entirely through the cul-de-sac under the upper lid; then the lower cul-de-sac is to be swabbed out in the same way, so that the silver is applied to every part of the conjunctiva. This, of course, cannot be done with children. We have to be satisfied with a less thorough application, which, however, will usually be sufficient. A certain amount of reaction invariably follows, but this can easily be controlled by iced cloths, and the irritation is of small importance compared with the seriousness of allowing the gonococci to penetrate the conjunctival tissue, which they always do with great rapidity. No other germicide is so much to be depended upon in this connection as silver. If the gonococci have penetrated, the swelling will have begun and the discharge will be profuse, and stronger solutions of silver may be necessary. When the disease is well developed, as it is apt to be by the third or fourth day after infection, the two-per-cent. solution gives the best results; but before that time stronger solutions may abort the process.

It is impossible to lay down any rule as to the limits of the time when the abortive plan of treatment may be used, but my own practice is always to attempt it wherever there is any prospect of success. If I see a case two days after infection, and the swelling or discharge seems not to be at the greatest height, I apply a three-per-cent. or a four-per-cent. solution of nitrate of silver as thoroughly as possible, and then meet the further indications as they arise, using 2 per cent. as a daily application. It is best in using a stronger solution than 2 per cent. to neutralize with salt-solution on account of the danger of staining the cornea, or even to lay a pledget of cotton soaked in salt-solution upon the cornea while making the application.

Where silver irritates, as shown by the increased discharge of serum, and a tendency of the conjunctiva to bleed readily when handled, a six-per-cent. solution of protargol may be used. It has been claimed for this germicide that it is without irritating properties, but this is certainly not so. It is, however, very much less irritating than silver, and many persons do not feel the application of a six-per-cent. solution at all. Stronger solutions are of no particular advantage—the irritation is more marked and the germicidal properties seem to be not appreciably greater. Protargol is a valuable drug in ophthalmia neonatorum—in cases in which the conjunctival thickening is not great enough to support applications of nitrate of silver. It may be dropped into the eyes twice daily.

In other forms of purulent discharge, that is, those caused by the pneumococcus, Koch-Weeks' bacillus, or other pus organisms, silver is not to be used, but protargol in six-per-cent. solution, applied once a day, is a most efficient germicide, and will often limit an attack of "pink eye" to a few days, which otherwise would last two or three weeks. Protargol has the further advantage of not staining the tissues as readily as silver nitrate; and it is good practice to flood the corneal ulcer occurring in the course of a gonorrhœal conjunctivitis, with a six-per-cent. solution once a day. It has been claimed that protargol will not stain the conjunctiva, but cases

*Read before the Medical Society of the State of New York at Albany, January 27, 1903.

have been reported in which its prolonged use has led to a slight stain. The claim at first made for it that it will penetrate the tissues and destroy germs more deeply than silver, seems not to be borne out by clinical experience. In severe cases of gonorrhœal conjunctivitis with papillary hypertrophy the astringent action of the silver is to be desired, and the discharge subsides less readily under protargol than under silver. Argyrol, 25 per cent., or silver vitelline, fulfils all the above indications for protargol, and is absolutely non-irritating. It also is less effective than silver when an astringent is required; but when a non-irritating germicide is required, it is certainly ideal. I have recently seen it injected into the anterior chamber of an infected eye with remarkable checking of the process, and without any irritation to the iris whatever.

The other indications for treatment in purulent conjunctivitis are best met on the old-fashioned lines. Constant cleansing with saturated boracic-acid solution resists the development of corneal ulcers and keeps down the number of germs. Boracic acid is merely a non-irritating wash and has no germicidal value. If we use plain water on the conjunctiva, or any other mucous membrane, there is a tendency to exosmosis set up at once in the blood vessels, which dilate—a phenomenon frequently observed when the eyes become red after being filled with tears in weeping. The least irritating solution, therefore, is one which has nearly the same specific gravity as the blood. The cleansing should be done often enough to keep the eye clean, even if that is every ten minutes day and night.

For the swelling of the lids, iced cloths applied constantly are best, and these have another very important action, as has already been pointed out, in reducing the temperature of the conjunctival cul-de-sac below the point at which pus organisms grow best. It is possible to reduce the temperature several degrees, while heat cannot be applied constantly, and most pus germs bear slight degrees of increased temperature better than diminished temperature.

Corneal complications are to be met on the usual lines, the only advance in recent times being the use of protargol or argyrol, either of which will destroy the germs in corneal ulcers as well as in the conjunctiva, and that without the irritation and danger of staining which makes the use of silver in this connection impossible. In a certain small proportion of cases, when the chemosis is severe and the discharge not free, scarification of the chemosis is of value, notwithstanding the fact that it has fallen into disrepute of late years, the reason for this latter fact being that its advocates at first claimed a much wider field for its application than was justifiable, as is so commonly the case with methods and remedies in this disease. Scarification will not reduce every case of chemosis, by any means; but in certain cases when the discharge is scanty and the chemosis is of a boardy character, scarification will relax the chemosis in a way that no other means will accomplish.

Cauterization of the cornea, in cases in which the chemosis is not severe, is a most valuable means of combating corneal ulceration, and is particularly useful in ophthalmia neonatorum. Pure carbolic acid is the best cauterizing agent to use. It need hardly be said that we should be reasonably certain that the tissues will react well to the cautery, which will not be the case if the chemosis is very severe, or if the patient's general condition is much reduced. When corneal infection appears, hot-water applications are to be used for the purpose of stimulating the corneal tissues.

NOTES ON CASES TREATED BY VENESECTION.

By GEORGE PIERCE ANDREWS, M.D.,
HONOLULU, HAWAII.

My good fortune brought me early in my career into close relations with Drs. Pitcher and Stewart of Detroit, both veterans in the profession, and who were conservative believers in venesection at a time (1862) when the thumb-lancet was hardly considered a necessity in the armamentarium of a physician. My experience has confirmed me in the belief in the value of bloodletting as a resource in varying emergencies.

Case I.—A robust, healthy young primipara was normally delivered after a natural labor. Soon after the birth was complete violent convulsions supervened; the medical attendant watched her for a time and went home to breakfast, saying she would be all right. Soon after I was called; the woman was unconscious and the eclamptic attacks of the most violent character recurring every few minutes, and each one seemed to threaten life. As soon as possible I opened a vein and took ten or twelve ounces of blood; relief was very prompt—I believe there were only two subsequent attacks. Besides the bleeding, I gave chloroform, both by inhalation and the stomach. Convalescence was uneventful and complete. I attended her once or twice afterward in normal labors.

Case II.—W., an old man of seventy years or more; a hard drinker, with degenerate arteries and probably heart. Was taken with catarrhal pneumonia, I think double. The case seemed desperate from the first. I gave supporting treatment and watched the heart. After three or four days there were signs of commencing pulmonary œdema and speedy death. Just then my old friend, Dr. Zina Pitcher, whose place in St. Mary's Hospital in Detroit I had been filling, returned. He at once *bled* the patient, who promptly rallied and in a few days was convalescent. The reduction in blood volume relieved the almost overwhelmed right heart and gave the sympathetic a fillip that saved the patient.

Case III.—Mrs. S., aged thirty-two years, in fair health, of nervous type; miscarried at four months; attended by convulsions, not very severe. A small venesection controlled all symptoms and convalescence was speedy. The patient was of full habit, with plenty of red blood. The abstraction of a few ounces of blood relieved the tension and restored the balance.

Case IV.—An old German, sixty years of age, of small stature and the sparest habit; might have sat for the "old woman" who "dried up and blew away." The last physique one would select for depletion. Had been for years a great sufferer from spasmodic asthma. The present attack had lasted for several days before my visit. I found him leaning over a table, resting on his elbows, laboring with all his might for air enough to sustain life. The friends said bleeding was the only relief for him, and that his physician resorted to it. I took six ounces of blood, and in five minutes he was breathing like an infant asleep.

Case V.—Mr. H., aged sixty-two years, a fairly healthy man, rather stout; a lawyer; subject to attacks of indigestion. A perfectly temperate man and a careful liver. Just previous to the attack he complained of severe pain just above the left orbital notch, and the family noticed that he hesitated in speech. Presently he fell unconscious and convulsed. I saw him within a half hour; he was then partially conscious; hemiplegic, pulse small, countenance pale; quite aphasic. There had evi-

dently been a small effusion of blood near the seat of pain. Treatment expectant. Gradually he recovered, completely to all appearance. The aphasia gradually disappeared. About one year later he fell in a second attack, in the street. This time the convulsions were violent and recurred frequently for an hour or more. Pulse full and hard; it seemed as if each attack would be fatal. Finally we took ten or twelve ounces of blood, with immediate relief to all the symptoms. The next day he was comparatively well; the aphasia quickly disappeared.

Some months later he had a return of the supra-orbital pain and slight confusion of speech. I bled promptly with relief to the symptoms. Subsequently the same thing happened, repeatedly and always with the same result. I believe once there was a recurrence of convulsions; he lived a number of years and died of some acute disease. The convulsions were distinctly epileptiform and seemed to be a direct sequence of the first hemorrhage. Undoubtedly it left a permanent lesion that was a source of irritation whenever there was hyperæmia.

Case VI.—Mr. C., a clergyman, over six feet in height, of extremely spare habit, aged eighty-two years, had suffered for many years with cardiac dyspnœa. At twenty-five years of age he had an attack of acute pleuritis (*sic.*), for which he was bled; and his physician continued venesection for the dyspnœa, which became habitual. The old gentleman had been bled every three or four weeks ever since. I was called to see him by his daughter, who gave me the above history and said, anticipating my objections, that it was of no use to argue with him, he would have relief, consequently I examined the patient, but could find no well-marked cardiac lesion. I regarded the symptoms as largely functional and due to habit. There might have been a slight aortic stenosis, but I detected no murmurs. He was in severe distress for breath and I took six ounces of rich dark blood, with immediate and complete relief. The flexure of the elbow in both arms was a curious sight, the track of the veins being a mass of cicatrices; it was a puzzle to find a clear point to insert the lancet, and the old man was a connoisseur in venesection; I was fortunate enough to secure a good stream, though subsequently I sometimes had to try two or three times. For two years I repeated the performance quite regularly every three weeks. At the end of this time he died. During the last few weeks of his life I did not see him, and I do not know just how the end came. The dyspnœa was not a marked symptom, however. The family employed a homœopathic physician. A very interesting point was the rapidity with which the red cells were reproduced in an old and feeble man. The relief of the dyspnœa would continue for nearly the three weeks, and then gradually increase until unbearable. Apparently the heart muscle was adequate to take care of the blood volume up to a certain point, but beyond that there was a strain. The nervous element probably depended somewhat upon the specific gravity of the blood. The patient was a prominent Baptist clergyman in his day; a man of great intelligence and considerable education.

Case VII.—Capt. H., aged thirty-two years, master of a lake steamer; a well-built, vigorous-looking man; had had several hemorrhages, but the signs of pulmonary involvement were very slight. When I saw him there was rather severe pulmonary hemorrhage. Previously venesection had promptly controlled similar attacks, and this time a moderate abstraction had a similar happy effect, and he was soon at work. A few years later he was drowned by the wreck of his boat.

Case VIII.—Mrs. McM., aged thirty-five years; married; a fairly healthy but corpulent woman. The menstrual flow was irregular after passing over a period. At such times she suffered with terrific migraine. A small abstraction of blood afforded relief and generally established the flow.

Case IX.—Mrs. A., aged twenty-three years; a very stout woman; primiparous about the eighth month. She had suffered an attack of scarlatina within two or three years and it had left renal complications. There had been œdema and scanty urine for a time, but I had only seen her a few days before I was called in the night to relieve excruciating pain in the back of the head; but before I could reach the house she went into violent convulsions. I found her unconscious, the paroxysms recurring every few minutes. I gave chloroform and bled as soon as possible and put her in a hot bath. Dr. W. P. Mantle saw her in consultation, and we proceeded to deliver as soon as possible, but the case went on to a fatal termination, which occurred about eighteen hours after the first eclamptic attack. Evidently the systemic intoxication was so profound as to overwhelm the cerebral centers.

Case X.—Mrs. W., aged twenty-three years, I-para, a well-developed, healthy young woman; labor normal under the care of Dr. F. R. Day of Honolulu. Convulsions began soon after the completion of labor; moderately severe and persistent, in spite of chloroform and sedatives. In consultation I advised bleeding; eight ounces afforded immediate relief, and convalescence was uneventful.

In all the above cases, except the ninth, relief followed the flow of blood promptly; in several of them when other means had failed. In each case bleeding was curative, in the sense that it tided over an emergency. Its action is, first, upon the volume of the circulation; second, upon the nerve centers, and is in the nature of shock; third, in certain instances, when the patient is conscious, the effect of expectancy upon the imagination is marked and benign, as in cases IV, VI, and VIII. I have never seen any notable ill effect or depression dependent on the loss of blood.

Immense Increase in Immigration and Objection to Women Inspectors.—Commissioners of Immigration from New York, Philadelphia, Boston, and Baltimore recently held a conference—mainly for the purpose of discussing the question of handling immigragrants in transit. All the commissioners were agreed that this year promised to beat all records for the arrival of immigrants in this country. The Baltimore commissioner said that 36,000 had been admitted into that port during the first four months of this year, while only 47,000 had been admitted during the entire twelve months of last year. According to the Boston Commissioner, the rush of immigrants showed a similar increase there. The conference also discussed the question of women inspectors. All agreed that the trial given them in New York had resulted in failure, and all the commissioners decided against introducing the system in harbors where it has not yet been tried.

Quarantine Order in Vermont Modified.—It is announced from Washington that Secretary Wilson has issued an order modifying the quarantine restrictions on the movement of animals and animal products from or across the State of Vermont.

ON THE ACTIVE PRINCIPLE OF RHUS DIVERSILOBA (POISON OAK).*

By CARL SCHWALBE, M.D.,
LOS ANGELES.

THERE are five different species of the genus rhus in Southern California. Of these five species (rhus diversiloba, trilobata, integrifolia, laurina, and ovata) only R. diversiloba is poisonous. In the year 1865 John M. Maisch published a preliminary notice: "On the Active Principle of Rhus Toxicodendron." Since that time there has been no publication on the chemical constitution of this very interesting poison till 1897, when Franz Pfaff, M.D., Ph.D., professor of the Pharmacological Laboratory of the Harvard Medical School, made his examinations, "On the Active Principle of Rhus Toxicodendron and Rhus Venenata." (*The Journal of Experimental Medicine*, Vol. II, No. 2, 1897). Pfaff proved beyond a doubt that the so-called "toxicondric acid" of Maisch is acetic acid, and that the active principle is an oil, which has as yet not been analyzed. Pfaff extracted the "toxicodendric acid" out of the fresh leaves with steam, prepared the baryum salt of the watery solution of the toxicodendric acid and proved by analyses that the acid was acetic acid. Maisch, when he prepared his so-called "toxicondric acid," suffered from a copious eruption and the formation of numerous vesicles on the back of his hands, fingers, wrists, and bare arms. Several persons coming into the room, while he was engaged with it, were more or less poisoned by the vapors diffused in the room, and the poisonous effects were even transferred to some other persons merely by shaking hands with them. It is very remarkable that Maisch did not have any eruption on his face. There is no doubt that the skin of the face is very susceptible to the poison of the rhus toxicodendron, venenata, and diversiloba. The fact that Maisch did not have any eruption in the face is a good proof that in his experiments the poison was not as a gas in the room.

Those persons affected by the rhus toxicodendron in the laboratory of Maisch, knowing that they had not touched the plant, were not poisoned by gases, they were affected in the same way as those shaking hands with Maisch. Pfaff (*l. c.* page 195) says: "I have used more than 25 K of fresh poison ivy and a few K of poison sumach. Hundreds of persons passed through the laboratory during the time that these plants were handled, extracted, distilled, etc. In not one single instance was a person poisoned who did not come into actual contact with the plant or free oil.

In opposition to Pfaff, A. Davidson, M.D., our able botanist (dermatitis venenata, *Southern California Practitioner*, March, 1897), says: "Many people handle the poison oak with impunity, others at certain seasons cannot pass within some 100 yards of the plant without being affected, and between these two extremes there are innumerable grades of intensity."

Louis L. Frank, M.D. (Remarks on Rhus Toxicodendron, MEDICAL RECORD, April 16, 1898), mentions some cases in which one person communicated the poison to another. The first is described in an article written by Dr. White (*New York Medical Journal*, 1873) reporting a fatal result in consequence of the poison.

"A servant boy, being insusceptible to ivy poisoning, had been employed in pulling up all the vines of that plant found growing in the grounds about the house. When his task was finished he was made to wash his hands thoroughly with hot water and soap, and afterward with vinegar. In the afternoon he was allowed to take the six-year-old child of the family to a pond for a bath. Having stripped the child, he immersed him, holding him with his hands under the armpits, and every part touched by the hands showed the characteristc mark of wild ivy poisoning."

Another case, reported by Dr. Cantrell (*Medical News*, 1891), shows how the poison was conveyed to the umbilical region of a female patient of the Philadelphia Hospital; a vesicular and bullous eruption having a radius of five inches, œdematous and covered with a yellowish-brown discharge, appearing three days after confinement. Upon inquiry it was learned that on the day of birth the attending nurse, taking a stroll through an adjacent cemetery, had gathered some leaves, bringing a number back with her. The ivy poison was in all probability conveyed to the patient during the time of dressing, although the hands of the nurse had been previously washed several times with soap and water. Her hands at that time showed no signs of infection, became affected two days later at about the same time when the eruption appeared on the abdomen of the patient.

A third case is mentioned by Dr. Busey (A. T. of Medical Science, Vol. XVII) in which a family, consisting of both parents and an infant, was affected at the same time, the mother having a severe attack quite general over the whole body, the husband a similar eruption on both hands, and the infant a slight one about the mouth and chin. A week previous to the appearance of the eruption, the husband and wife had passed an afternoon at a picnic and he had fastened his horse to a bush, covered with a vine, the character of which he had not observed. The wife did not approach the plant and the child had been left at home.

Dr. T. B. Walker (*Medical News*, 1891) reports the fourth case of poisoning by indirect contact. A lady spent the night with her sister whose husband was obliged to be absent on business. The husband had been poisoned about the head and neck with ivy a few days before leaving home. The pillow case on which he slept was not changed, and his sister-in-law using it, became poisoned about the face and neck in consequence thereof. These four cases, as I mentioned above, have been collected by Dr. Frank. These facts prove that in most of the cases there must be a solid particle of the rhus plant making the poisoning on the human skin and not a gaseous matter. I made the microscopical examination of the plant and found the explanation of this fact. There are in the leaves, in the skin of the stems and stalks of the leaves and flowers, and even in the petals, lactiferous vessels containing the poisonous matter of the plant.

Upon these vessels grow hairs, loaded more or less with the poisonous oil. These hairs are prevalent on the stems, on the under surface of the leaves and even on the petals of the plant. The hairs derive the poison by osmosis from the lactiferous vessels, and are carried, when broken off, easily by the wind or by the help of man or animals to persons liable to the affection. The presence of the hairs on the stem during the winter, when there are no leaves on the shrub, explains the fact of the poisonous qualities of the plant even in winter time. Generally the hairs penetrate into the opening of the sudoriferous and sebaceous glands, and this observation is corroborated by the fact that those parts

*Delivered before the Southern California Academy of Science.

of the skin perspiring easily are affected most frequently.

Persons perspiring very easily are, as a rule, more liable to the affection than those without a moist perspiration. I, for instance, scarcely ever sweat, and am not subjected to the effects of the poison when I go to places where the rhus diversiloba is growing. The same is the case with my wife and my children. When I smear the milky juice between my fingers I am locally poisoned. With a microscope of 90 diameter it is easy to locate on the skin the hairs, and those oily substances exuding through the walls of the hair and being fixed as irregular lumps on the outside of them. These irregular lumps are very probably in most cases the immediate cause of the infection. The hairs of course can remain in the openings of the sudoriferous glands for several days in spite of washing with soap. The neutral soap does not destroy the poisonous toxicodendrol. There is an alkali necessary—for instance, carbonate of potash, well known to everybody as concentrated lye. A one-tenth to one-half per cent. solution as a washing several times a day when there was a possible contact with the poison oak, is sufficient to protect everybody against the bad effects of this interesting plant.

A. T. Hudson, M.D. (New York Medical Record, July 30, 1898, Page 173), recommends very highly a solution of muriate of ammonium (1—1½ per cent.) as a prophylactic and remedy. Frequent washing with the solution is necessary. Everyone using one of these two remedies frequently, at the right time and in necessary amount, will be exempt from the danger of this much-dreaded poison oak (rhus diversiloba).*

*In the *Münchener Medicinische Wochenschrift*, April 8, 1902, Dr. Dreyer publishes a case of dermatitis, the effect of the poisonous hairs of Primula obconica. The chemical composition of the poison contained in the hairs is not known.

1002 South Olive Street.

REFLEX SYMPTOM FROM BILIARY CALCULUS.

By G. W. SQUIRES, M.D.,
EAST AVON, N. Y.

The diagnosis of diseased conditions by symptoms is oftentimes a puzzle to the most astute. The organs of the body are so closely knit together in physiological sympathy that the cause of the symptom may lie far remote from the seat of the apparent difficulty. The following case, which occurred in my practice, I wish to report as a unique experience to me along this line of distal irritation: Mrs. T., of Canadian birth and aged fifty-two years, had suffered for fifteen years by what was supposed by many physicians to be dyspepsia, with occasional attacks of acute indigestion, accompanied with vomiting, the seat of the distress always being located at the cardiac end of the stomach. After a few days of gastric difficulty and through emesis the digestion recovered its usual tone of lowered vitality, and with great care in dietary the patient, a busy woman, accomplished much work of the household sort. About eighteen months ago this patient began to notice and complain of what she described to be at first a stiffness, then a tenderness followed by a pain in the heels directly over the region of the tendo achillis. On examination nothing could be discovered, after exercise, which was difficult and painful at first, the parts felt better and limbered up so the person could walk quite a distance, but with a curious ambling, flat-footed gait. In the morning, with or without exercise, the heels were so stiff that the woman had difficulty in moving around. Now an eruption suddenly appeared on the right heel four inches long by three wide over the tendo achillis—a typical herpetic rash; in two days the left heel was effected in exactly the same manner. The suffering the woman endured with this eruption seemed out of proportion to the local affection; the pain radiated from the heels up the legs to the body and came in paroxysms of such distressing intensity as to cause the sufferer to cry out. Nothing local or internal seemed to benefit the eruption on the heels. Hypodermic medication of morphine and atropine would allay the cramps, only to return when the medicine had spent its effect. Suddenly the seat of war was transferred to the region of the gall-bladder, a typical biliary colic set in with a vigorous attack. Whether the heel and leg pains were less or the biliary distress so much greater, the patient now complained most bitterly of the distress in the side; constipation and jaundice now set in. Hypodermics of opiates were frequently demanded, but with large doses of salts and calomel the bowels were practically unmoved for two weeks; olive oil, in large quantities per mouth, and rectal enemata failed of catharsy; a few clay-colored lumps were passed; no bile was passing into the intestines, the patient was becoming alarmingly jaundiced, the whole body saturated with the bile pigment. More calomel was advised on consultation, and insisted upon by the family, until the patient was badly salivated. Suddenly the patient gave a sigh of relief and remarked to the nurse that something had broke loose in her side and she felt relieved of the distressing pain, calling at the same time for the bed-pan, as she felt a desire to move the bowels. After a few minutes a free bilious dejection took place, and the patient relapsed into the first refreshing sleep that she had experienced in two weeks. The nurse, as had been directed, examined the dejection by washing through a sieve with water, and found a calculus the size of a pigeon's egg with four sharp prongs on its elongated sides. The pain and eruption of the heels almost immediately subsided, the jaundice cleared up, the indigestion disappeared, and the patient got rid of all her former complaints, and is to-day what one could well call a healthy person.

Retinal Hemorrhages as a Diagnostic Feature in Fracture of the Base of the Skull and in Subarachnoid Hemorrhage.—R. A. Fleming reports a number of cases which show that a subarachnoid hemorrhage, if sufficiently rapid in its development, will cause retinal hemorrhages, and that if the effusion is unilateral the hemorrhages will be confined mostly to the affected side. In fractures of the base the diagnosis is by no means always easy. In fractures involving the anterior fossa of the skull there is often bleeding or escape of cerebrospinal fluid from the nose, or discoloration in the neighborhood of one or both eyes, due to extravasation about the sphenoidal fissure. Where the fracture extends to the petrous part of the temporal bone, bleeding or escape of cerebrospinal fluid may be noted from the ear of the affected side. But where, on the other hand, the posterior fossa is the site of fracture, the diagnostic phenomena are very uncertain; although discoloration behind the mastoid, and sometimes a more diffuse discoloration in the neck, may be noted. The recognition of retinal hemorrhages is easy even to the comparatively inexperienced ophthalmoscopist, and the importance of these hemorrhages can be best realized by a study of the cases submitted by the author. Where the subarachnoid hemorrhage comes on gradually, no retinal hemorrhages are produced. It is well known, for instance, that retinal hemorrhages are not a necessary result of the great but gradually increasing pressure, such as may occur in cerebral tumor, internal or external hydrocephalus, etc.—*The Edinburgh Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 30, 1903.

THE CAUSE AND TREATMENT OF EPILEPSY.

As to the cause of epilepsy, nothing really definite is known, although the most common belief amongst those who have made a special study of the disease is that it is of toxic origin. Drs. Clark and Prout in their recent paper in the MEDICAL RECORD, say: "In considering the development of the disease, we believe the excitant is a toxic or autotoxic agent for the following reasons: First, the lesion is a general one affecting the entire cortex; second, it involves most extensively the cells of the second or so-called pyramidal type, the cells which present a relatively larger surface exposure to the circulating poison in proportion to their volume than the large pyramids; third, the presence of a marked neurogliar proliferation; fourth, the changes in the cell are quite analogous to those definitely known to be caused by toxic agents, as furfural, alcohol, and the tetanus bacillus and its toxins."

On February 9, at a meeting of the Medical Society of London, epilepsy was made the subject of discussion, and the views of some of the best known of the British authorities upon nervous diseases were set forth.

Dr. J. S. Risien Russell said that "The true cause of epilepsy was as yet unknown." The theory that epilepsy resulted from an autointoxication was that most generally received, although it could not be looked upon as proved. Some thought that microorganisms were the cause, but here again there was no satisfactory proof. Treatment had been initiated which presupposed that epilepsy was due to the action of some poison which reached the nerve elements by way of the blood stream, and experiments had been made in line with this theory. Epileptic patients had been inoculated with filtered cultures of streptococci and staphylococci, erysipelas toxin, or antitoxin. Dr. Russell, however, was compelled to admit that the bromides were still the most potent agents for the treatment of idiopathic epilepsy. A free administration of the drug was indicated. Whichever of the bromide salts was used, a single dose should be given an hour before bed-time in nocturnal epilepsy, and two hours before an attack was due when the fits recurred at about the same time in the day. It was better to increase the single dose up to one drachm or more than to give it in divided doses several times a day. In considering what dietetic and other measures aided in securing success, for the bromide treatment the importance of prohibiting stimulants, including tea and coffee, was well recognized. These patients did best on a diet which contained only a small amount of meat. The most important modification that had been introduced into the dietetic treatment of epilepsy during recent years was the exclusion of ordinary salt from the dietary, but this had been suggested by Dr. J. Hughlings Jackson thirty years before.

Sir Victor Horsley said that he would classify epilepsy according to its causation into four groups: (1) Idiopathic epilepsy in which there was no no gross lesion. This might be localized or generalized onset, but neither of these cases was very suitable for operation. He had, however, operated on five cases of the former. Two of the cases had proved to be of organic origin. These showed that an exploratory operation might be justifiable in cases which had resisted medical measures. (2) In Jacksonian epilepsy there existed always a gross lesion or a toxæmia. In traumatic cases of a Jacksonian type the convulsions might be generalized or localized. In the former, surgical measures were not by any means uniformly successful; in localized cases, however, trephining was very successful, particularly when the scar was in the so-called motor area; it was less successful when the scar was in the occipital region, and still less successful when it was in the frontal or temperosphenoidal region. Cases of congenital focal epilepsy did fairly well when operated on in early childhood. Cases of neoplastic origin were, of course, very amenable to surgical measures. The fits in such cases were not always localized; they might be so generalized as to resemble idiopathic epilepsy. (3) Reflex epilepsy might arise from injury to a nerve, injury to the spine, or from traumatism. (4) In hysteroepilepsy no operation should be performed, although ovariotomy and other procedures had been employed by some.

These then are the opinions of two of the foremost authorities in Great Britain with regard to the cause and treatment of epilepsy, regarded from the medical and surgical point of view. In the discussion that followed the reading of these papers, most of the speakers expressed themselves as somewhat sceptical as to the toxic origin of epilepsy, were agreed with regard to the great value of the bromide treatment, albeit some did not altogether believe in heroic single doses of the drug, but rather placed their faith in smaller doses more frequently administered.

Drs. Clark and Prout, in the paper referred to at the commencement of this article, concluded as follows: "We submit that epilepsy is a disease resulting in diffuse and profound cortical degeneration; a highly complex sensory motor phenomenon, primarily sensory with a motor expression. The lesions attending its course are shown in the following: Swollen nucleus, destruction of the nuclear membrane and intranuclear network; easy abstraction of the nucleolus by the knife, as it becomes a loose body in the nucleus; diffuse chromotolysis, and other protoplasmic changes. All these lesions result in the ultimate disappearance of the cell as a biologic unit and its replacement by a gliosis. The lesions are induced by a toxic

or autotoxic agent operating upon an organic anomaly of the cerebral cortex which forms the predisposition. We urge, therefore the construction of special accommodations for the reception and study of each newly admitted case of epilepsy in the colonies, and hospitals which shall be arranged on similar lines to the psychopathic hospitals abroad, and we finally suggest that some central advisory committee be appointed to formulate a correlated plan for future study and research."

The situation as regards epilepsy, therefore, would appear to stand thus: There is no definite knowledge as to its cause, but at the same time a large number of those who have carefully studied the matter are of the opinion that the disease is of toxic or autotoxic origin. This view is based upon the analogy of the cell changes in epilepsy to those produced by toxic agents. It is, however, of the utmost importance that the problem of the cause of epilepsy should be solved, for by its study and solution many obscure points in neurology and psychiatry will be cleared up. In order to bring about this consummation, every facility for investigating the phenomena of the disease under the most favorable circumstances must be available. Consequently, if the neurologists of the United States desire to take a leading part in elucidating the obscure features of epilepsy, the plan of research suggested by Drs. Clark and Prout to attain this end cannot but recommend itself to them. In the meantime, the bromides must be regarded as the sheet anchor in the treatment of the disease.

INFECTIVENESS OF MILK OF COWS WHICH HAVE REACTED TO THE TUBERCULIN TEST.

Dr. John R. Mohler, Chief of Pathological Division, Bureau of Animal Industry, U. S. Department of Agriculture, has recently published a bulletin relating to his investigations concerning the infectiveness of milk in a herd of cows, many of which died of rabies. The report, however, deals with tuberculosis in the herd, and not with rabies.

On May 2 and 3, some six weeks after the outbreak of rabies, the herd, then consising of 104 head, was tested with tuberculin. Two cows were excluded from the test. Of the remaining 102 head, seventy-six gave a decided reaction, while one cow showed a questionable rise, making the proportion of animals affected more than 74 per cent. Of the twenty-five animals which did not react, thirteen had but recently been purchased and had been kept in one line by themselves in a corner of the barn during the two weeks they had been in the stables. If these thirteen animals had been excluded, it can be seen that more than 85 per cent. of the old herd would have been tuberculous.

These results were sufficiently plain evidence that prompt and radical measures must be taken to prevent further spread of infection, and that those which, on physical examination, were found to be affected with any of the forms of tuberculosis which are especially dangerous for the dissemination of the disease, must be eliminated. This examination led to the selection of twelve head for immediate destruction, and accordingly they were slaughtered. Ten of these animals had reacted to the tuberculin test; one was selected owing to the development of symptoms of traumatic pericarditis, while the twelfth had only shown a suspicious rise of temperature, scarcely high enough to be regarded as a reaction.

A careful post-mortem examination showed that the ten reacting animals were affected with tuberculosis to a greater or lesser extent, while the cow giving the questionable rise of temperature showed only three encapsulated tuberculous centers, the size of hemp seeds, in one of the mesenteric glands.

The remainder of the herd of ninety-two, sixty-six of which reacted, were divided. The reacting animals were isolated, and the non-reacting cows were placed in a separate barn which had undergone the most thorough and careful disinfection.

It was then determined to ascertain, through feeding and inoculation experiments, whether the milk from the affected cows contained virulent tubercle bacilli, and, if so, to what extent. The experiments to prove this point were conducted with the most approved methods, guinea-pigs being used as experimental animals.

The results were as follows: The milk of 16.07 per cent. of fifty-six reacting cows was found to be pathogenic to guinea-pigs when fed to them. Of the experimental animals inoculated intra-abdominally in the first series, at least one guinea-pig died of tuberculosis in each of six different instances, showing that the milk of 10.9 per cent. of 55 reacting cows in this experiment proved fatal to guinea-pigs in the first inoculation experiment. In the second series of intra-abdominal infections, the milk from seven individual cows out of forty-five examined, or 15.5 per cent. was demonstrated to possess virulent tubercle bacilli. By uniting these inoculation results, it will be observed that eleven out of fifty-five cows, or 20 per cent., secreted milk which transmitted tuberculosis to one or more experimental animals when injected into the peritoneal cavity.

Owing to the greater percentage of positive results obtained from a second inoculation experiment, conducted more than two months after the first intra-abdominal test, it appears probable, as would be expected, that the virulence of milk increases with the advancement of the disease in the cow. The lack of uniformity of results obtained in many of the cows might be explained from our knowledge that tubercle bacilli are not excreted by the normal udder with any degree of constancy. For this reason the continuous feeding experiment, covering a period of three months, seems to have more practical value in demonstrating the transmission of tuberculosis than the inoculation test, where the only possibility of affirmative results must depend on the contingency of the accidental excretion of the bacilli on one particular day.

The combined result of the ingestion and inoculation experiments showed that the milk of twelve out of fifty-six reacting cows, or 21.4 per cent., had at one time or another since the beginning of the experiment contained virulent tubercle bacilli.

Dr. Mohler ends his paper with these words: "From the results of the experiments conducted in this laboratory, as well as from the majority of similar investigations, the following conclusions

regarding the infectiousness of milk from tuberculous cows seem justifiable: (1) The tubercle bacillus may be demonstrated in milk from tuberculous cows when the udder show no perceptible evidence of disease, either macroscopically or microscopically. (2) The bacilli of tuberculosis may be excreted from such an udder in sufficient numbers to produce infection in experimental animals, both by ingestion and inoculation. (3) That in cows suffering from tuberculosis the udder may, therefore, become affected at any moment. (4) The presence of the tubercle bacillus in the milk of tuberculous cows is not constant, but varies from day to day. (5) Cows secreting virulent milk may be affected with tuberculosis to a degree that can be detected only by the tuberculin test. (6) The physical examination or general appearance of the animal can not foretell the effectiveness of the milk. (7) The milk of all cows which have reacted to the tuberculin test should be regarded as suspicious, and should be subjected to sterilization before using. (8) Still better, tuberculous cows should not be used for general dairy purposes."

The most striking feature of Dr. Mohler's investigations would seem to be the confirmation of the value of tuberculin as a diagnostic agent. Whether, however, it would be practicable to exclude all cows which react to the tuberculin test from use for dairy purposes is another matter. The number of cows affected to a greater or less degree with tuberculosis is enormous, and so long as the point in regard to the danger of milk containing tubercle bacilli as human food is unsettled, it would, perhaps, be asking too much of herd owners that they should not use animals which have reacted to the tuberculin test for dairy purposes. On the other hand, there can be no doubt that every possible step should be taken to extirpate tuberculosis in cattle, and to safeguard the public from the menace of infection by such means.

COMPENSATION FOR MEDICAL SERVICES RENDERED THE STATE.

THE services of the physician are everywhere inadequately recompensed. At any rate, such is the firm belief of the majority of the members of the medical profession itself. They hold that they are paid proportionately less for the work they do, than those of any other educated class. Lawyers, for instance, are, as a rule, remunerated far better than are doctors. It is a curious commentary on the materialism of the age, that property is considered more valuable than life, or rather that an individual is willing to spend more to save his property than to benefit his health.

Dr. T. D. Davis of Pittsburg, Pa., read before the American Academy of Medicine, a paper which embodied these views, and he further considered the matter from the standpoint of the State and the physician. Governing authorities act toward the physician in exactly the same way as does the individual, only in an exaggerated degree. They regard health compared to property as a secondary consideration, at least their actions seem to favor such an interpretation of their sentiments. For example, Dr. Davis points out that governments compensate their legal talent much more liberally than their medical talent. That they do thus discriminate, he proves by comparing the compensation of the legal and medical officers of four large cities of the United States. Dr. Davis after thoroughly probing the question shows that the salaries of the lawyers are from two to three times that of the physicians, or $6,000 for the heads of the legal departments to $2,400 for the heads of the medical departments. The city attorneys have a long list of assistants at from $2,500 to $3,500 per annum, while the assistant physicians in the health departments vary from $900 to $1,200 for the same time. In the smaller cities the difference is still more marked.

The writer thinks that the reason for this state of affairs is because physicians undertake their own services, and that there is no remedy for it but through the profession. In the past it is possible that many doctors underrated their services because they obtained their education in a very short time and quite inexpensively, and so valued their knowledge accordingly. But under present conditions the medical course is quite long enough and sufficiently expensive to demand higher emoluments for its graduates.

Dr. Davis then touches on a matter which cannot but appeal forcibly to every medical man—that is, the custom of giving gratuitous service. An example of this ill-advised charity is the free treatment of clergymen by physicians. Both professions are injured by this proceeding, the one by cheapening medical services and the other by a certain loss of self-respect. Again, medical men, by their eagerness to accept positions with paltry stipends in State institutions, do not tend to impress public officials with the exalted views of the value of medical knowledge. The craze existing among members of the medical fraternity to become attached to hospitals and institutions of a like kind without pay, renders public officials liable to underrate the value of their services. Although a person is not altogether taken at his own valuation, yet there can be no doubt that extreme modesty as to one's qualifications is not the best way to get on in this world.

Dr. Davis asserts, too, that frequently "the game is not worth the candle," and that the practical advantage of being attached to a hospital, to a diligent physician, who is not a teacher, is wonderfully overestimated by the profession. The writer is of the opinion that the time consumed, absence from office, and study outweigh the advantages of the large practice, while hospital matters cannot be successfully transferred to the home or private practice.

Whether this be so or not, there can be no doubt, that Dr. Davis is correct in his contention that doctors are inadequately remunerated by the State, and he is also probably right when he gives as the chief reason for this discrimination against the medical profession, the backwardness of physicians to assert themselves. The fact, however, must be borne in mind that medical men are seldom politicians, while to the lawyer politics are "as the breath of his nostrils," and to the politician belongs the spoil. It would be well if physicians would take the advice of Dr. Davis to heart, and resolve to demand for their services the remuneration which is justly their due.

Congenital Displacement of the Hip.

The methods of Dr. Lorenz in treating congenital dislocation of the hip have recently been subjected to a certain amount of criticism. At the meeting of the American Surgical and Orthopedic Association just held in Washington, the matter was freely and fully discussed, some of those present expressing themselves as opposed to Dr. Lorenz's mode of procedure, while others warmly defended the manner of treatment of the Austrian surgeon. One and all spoke in the highest terms of Dr. Lorenz personally and professionally.

In view of the difference of opinion existing with regard to the most satisfactory plan to be adopted in the case of congenital displacement of the hip, it may be of interest to quote some of the views held by the well-known English orthopedic surgeon, Mr. Noble Smith, which are contained in an article contributed by him to the *Lancet*, May 2. He commences by laying down these propositions: (1) In all cases and at all ages some good may be effected by treatment. (2) If the displaced head of the femur has formed a firm bearing against the pelvis, so that no tendency to decrease of deformity exists, and the difficulties of walking are slight, then we may devote our energies to counteract lordosis by mechanical support, freeing adverse contractions, such as those of the adductors, and equalizing the length of the legs when only one side is involved. Sometimes when both sides are affected there may be inequality in length of legs. (3) If the head of the femur is freely movable up and down (telescopic) then some measures must be adopted to prevent increase of deformity, and the least that can be done is to recommend the use of some apparatus to keep the weight off the affected limb. Up to the age of seven years all congenital dislocations can be reduced. This is Dr. Lorenz's dictum, and his view seems correct. In single displacements the time limit may be extended to nine years of age. These limits are not absolute, for much older patients may occasionally have their hips replaced.

Mr. Noble Smith, referring to the treatment of congenital hip dislocation by Lorenz's methods, puts the subject in the form of questions and answers. Question: Is the so-called "bloodless" method of rupturing the contracted adductors, as advocated by Lorenz, satisfactory? Answer: In children up to the ages of four, five, or, perhaps, six years a very moderate amount of firm pressure and massage of the adductors, held tense, will rupture their fibers, and although a certain amount of extravasation of blood will take place beneath the skin and around the site of the rupture, the effect is satisfactory, and as some parents attach great importance to the avoidance of the use of the knife this procedure admirably serves our purpose. In older patients, or in any patients whose muscles are very firm, the section of the contracted part with the knife is better. Question: What are the comparative effects of the two methods of operation on the adductors, rupturing and cutting the fibers? Answer: The rupture of the adductors after Lorenz's method is effectual in overcoming the contraction, but besides causing extravasation of blood, it often leads to abrasion of the skin. Division of the right muscles through an open wound is a very safe and satisfactory procedure, but it is necessary to protect the wound with a sterilized dressing during the subsequent manipulations required in the reduction of the displacement. Mr. Smith says that he has found a combination of the two methods of operation satisfactory and effective.

England's Inebriates Act.

The new Inebriates Act which was recently passed in England is divided into four parts, the first part of which consists of provisions that affect the general body of English laws relating to the sale of intoxicants and the treatment of inebriates. The *Sanitarian*, April, contains an abstract of the whole act. In the first division two new offences are created: (1) Being "found drunk in any highway or other public place, whether a building or not, or on any licensed premises, appearing to be incapable of taking care of oneself." Such a person many be "apprehended and dealt with according to the law"; (2) Being "found drunk in any highway or other public place, whether a building or not, or on any licensed premises, while having the charge of a child apparently under the age of seven years." Such a person may be apprehended and shall, if the child is under that age, be liable, on summary conviction, to a fine not exceeding forty shillings ($10) or to imprisonment, with or without hard labor, for any period not exceeding one month. A person, who not being amenable to any jurisdiction in lunacy, is, notwithstanding, by reason of habitual intemperate drinking of intoxicating liquors, at times dangerous to himself or to others, or incapable of managing himself and his or her affairs was defined by the "Inebriates Act" of 1879 as "a habitual drunkard." The new act provides that the wife of such a man can apply for an order that she be no longer bound to cohabit with him; that the legal custody of the children of the marriage—while under seventeen years of age—be committed to the wife, and that the husband pay wife alimony in keeping with his circumstances. In case the wife be an habitual drunkard the husband may apply for a corresponding order, and the court may decree that the applicant besides being free from the obligation to cohabit with her, shall have the custody of the children and shall pay a reasonable sum for her support. In place of the provision with regard to cohabitation the Court may, with the consent of the woman, order her to be committed and detained in any retreat licensed under the "Inebriates Acts." It is possible for the Court to detain any convicted inebriate in one of these retreats for a term not exceeding three years.

Dangers of Hypnotics.

The addiction of the general public to sleep-producing and pain-dispelling remedies is widespread and increasing. The Medical Record has frequently drawn attention to this fact, and has deplored the irresponsible misuse of otherwise valuable drugs. Americans are said—and the charge is hard to gainsay—to be especially prone to fly to hypnotics in order to obtain temporary relief from the nervous strain to which, as a race, they subject themselves. The stress and storm of life which goes with modern civilization is nowhere more apparent than in this country, and nowhere is the drug habit more prevalent. Dr. Nestor Tirard recently read a paper before the Therapeutical Society of Great Britain, in which he touched upon certain phases of this custom. He dealt with the following propositions: (1) hypnotics may all involve danger; (2) the conditions under which they may procure undesirable results are not always dependent upon the dose; (3) the danger may be limited to the patient; (4) the danger may involve the prescriber or the dispenser; and (5) before the employment of a hypnotic the bare symptom of sleeplessness is perhaps the least important factor to be considered. The writer demonstrates the truth of these propo-

sitions by examples drawn from his own experience. He shows that the prescriber and dispenser, as well as the patient, are often placed in danger by mistakes made by one or the other of the first two named, and that sometimes, through no fault of their own, they are placed in a dangerous position by the artful devices to obtain hypnotics resorted to by those who are given over to the drug habit in order to conceal the vice.

Dr. Tirard points out that the administration of some hypnotics by hypodermic injection is fraught with numerous dangers. He says: "The hypodermic syringe was full of risks when it passed into the hands of the public. It encouraged the frequent use of hypnotics, the formation of the drug habit, and it led to the employment of increasing doses and to the possession of strong solutions or of compressed drugs, which were always liable to be wrongly employed. The chief disadvantage of the hypodermic use of hypnotics is, however, to be found in the difficulty experienced when an overdose has been employed. When an over-dose has been taken by the mouth some of it may be returned by vomiting or by the use of an emetic, or by the stomach tube, or it may be rendered inert by the administration of some other drug, which may render it insoluble before it has been absorbed from the stomach. When given hypodermically, all these modes of treatment are barred, and the safety of the patient depends on the employment of a physiological antidote which may hinder activity sufficiently long to allow time for elimination." Regarding sleeplessness as a reason for giving a hypnotic, Dr. Tirard records his conviction that it is, perhaps, the least important factor to be considered. He contends that the cause must be ascertained, together with any indications of idiosyncrasy. Also, the co-existence of other diseases must influence the selection of the hypnotic, and even when, for the individual case, a suitable hypnotic has been found, risks of repeating moderate doses must be borne in mind. Generally the dose has to be gradually increased, especially when the cause has not been ascertained or satisfactorily dealt with. The writer deems that the greatest danger of all is incurred when the patient is given a prescription for a hypnotic. Armed with this, the patients commonly go on taking the drug long after the relief of the special circumstances for which it was prescribed, and the prescription may be used to facilitate the acquisition of large quantities of a dangerous drug, obtained, perhaps, at several establishments in small amounts. In consequence of the existing condition of affairs regarding the sale and use of hypnotics, Dr. Tirard states that he is in favor of any step that would tend to prevent the administration of hypnotics except by a medical man or under his immediate directions. He would likewise prohibit their sale to the public and would only allow them to be dispensed to a freshly dated prescription, which should be retained by the druggist or returned to the prescriber. Strict regulations with respect to the sale of hypnotics are badly needed in all parts of the United States. The law in many States is altogether too lax regarding this matter.

Abscesses of the Liver Following Typhoid Fever.

Dr. John Sheldon of Telluride, Col., in the *Journal of Medical Sciences*, April, discusses the above subject. He describes a case of abscess of the liver following typhoid fever which came under his notice, the infection originating by way of the portal vein. The writer is of the opinion that the colon bacillus is, in all probability, the organism which is most active in producing the so-called typhoid liver abscesses. In support of this theory the following facts are brought forward. (1) Colon bacilli are present in abscesses of the liver following typhoid fever. (2) Roger has shown that the liver promotes the growth of the colon bacillus, while it inhibits the growth of the typhoid bacillus. (3) Macaigne and Kleck have shown that the virulence of the colon bacillus is increased by disorders of the intestinal tract. (4) Sanarelli found that the colon bacillus, isolated from typhoid stools, were more virulent than when isolated from healthy stools. He thought that the increase in virulence is due to the effect of the typhoid toxins, and devised an ingenious experiment, which seems to prove this point. If it is true that the virulence of the colon bacillus is increased in a patient suffering from typhoid fever, and that the liver offers little if any resistance to invasion by the colon, it is not surprising that hepatic suppuration occasionally follows typhoid fever.

The organisms responsible for the reduction of hepatic abscesses following typhoid fever, according to the best authorities, reach the liver by way of the portal vein, the hepatic artery or the bile ducts. Infection through the portal vein seems to be the most common means of infection. Liver abscesses, after typhoid fever, due to infection by way of the hepatic artery, are more rare than the former manner, although there are several cases of this kind reported. The third method of infection of the liver, with abscess formation, by way of the bile tracts, is the rarest of the three modes. Klebs is the only one to report a case of this character.

The cases of liver abscess following typhoid fever, of which Dr. Sheldon could find a record, occurred in adult males aged from twenty-five to thirty-seven years. One case occurred in a boy of twelve years and another in a girl of eleven years. Jaundice is by no means a common symptom. Da Costa reports jaundice in seven of the twenty-two cases he has found recorded. Enlargement of the liver was almost always present, while ascites was found in one case of pylephlebitis. Suppurations in portions of the body other than the liver occurred in seven of the cases, either suppuration of the mesenteric glands or in other parts of the body. The diagnosis in all cases of liver abscess may be easy, difficult or virtually impossible. The prognosis of hepatic suppuration is always very grave, but cases do recover. The treatment is strictly surgical although Dr. Sheldon thinks that aspiration is sometimes of great use.

How to Be Successful as a Physician.

Under the above title a Meriden (Conn.) physician delivers himself of some "heart-to-heart" talks to his brother practitioners. The subject is trite, yet with a perennial interest, and if anyone can bring forward a panacea most of us would be glad to take it. All, of course, depends upon what one considers success. For the author the successful physician "is one who is well trained in all departments of medicine and surgery, and who can give the best possible service with the latest advancements in medical and surgical science, and earns a comfortable livelihood." The greater part of this readable little book, in which the vials of wrath are poured out in no measured terms upon the head of the incompetence, the charlatanism, and the chicanery of the day, seems to be directed to showing why so few succeed. At the outset the author compares the status of the practitioner with those of his compeers in the other two learned professions. The profes-

sional level of the law, he finds low and sordid; and that of the clergy, inane and vapid. We wish that the picture of the medical profession might be brighter, but for him there is quite too great a sprinkling of "half-baked" individuals, who come in for delineation in some very vigorous English, in the use of which the author shows himself a past grand master. For these shortcomings, the defective preliminary education of the average medical student, the poor quality of the instruction at most of our medical colleges, and the shortness of the time required to secure a diploma, are held responsible. Then, too, the medical man is beset on all sides by foes; the quacks and charlatans, the prescribing druggist and the free dispensary, and the patent medicine man, have all settled down upon him to eat out his substance. Indeed the title of the book before us might well be, How to Succeed *though* a Physician. For, as the writer says, there is an ominous decline of patronage in every department of professional work; in the larger cities comparatively few of the hitherto successful practitioners are overworked, and there is a falling off of from one-third to a half from the income of former years. Out of 135,000 physicians in the United States, 100,000, it is estimated, average only $1,000 a year. When we look for the remedy, the author offers a simple one—*work;* hard, unremitting application by way of preparation for the time when one may hope to be too busy to devote hours to study. The most important period for the physician, therefore, is the first ten years after graduation, and upon the manner in which those years are spent his future will, in great measure, depend. If one is to succeed, he *must* make himself competent, and that in the fullest sense of the word. As Booker T. Washington puts it, he must be able to do something the community wants done better than his neighbor can do it. Much good advice is given as to what is needed to constitute an up-to-date physician to-day. Ability to perform, on occasion, operations of emergency, such as intubation and tracheotomy; ability to make a Widal test, to recognize the *plasmodium malariæ*, to estimate the amount of hæmoglobin, and to make a blood count. All this, and nothing less, is expected. An up-to-date physician will, in short, be a good diagnostician, for this is where he shows, even to an intelligent laity, his superiority; especially in the avoidance of wobbling from day to day in the characterization of a case. For accurate diagnosis alone can lead to accurate prognosis. The author is especially severe upon the superstitious reverence even yet accorded to the Magical Prescription; the still lingering belief in the marvellous potency of drugs, which the strenuous zeal of our manufacturing pharmacist does so much to foster. Finally, to be successful the physician must be a gentleman and a collector. As the last page announces "Heart-to-heart Talks, No. 2; How to Be a Successful Clergyman," our legal brethren will probably not languish long unprovided for.

New Diploma Selling Institution.

Of diploma-selling institutions there is a plethora in this country, and the United States would seem to be the happy hunting ground for the exploitation of such projects. A new one has recently been floated in Chicago, to which as been given the high-sounding name of Christian Red Cross Hospital. The medical and surgical staff includes some well-known names, among which is that of one of the most distinguished surgeons in this country, a man of world-wide reputation.

The inducements set forth in the circulars issued to medical men to join this institution are many, some of which are as follows: "Our Certificate of Membership is artistically designed, and executed in the highest style of the lithographers' art, neatly framed and hung on the walls of your reception room, it imparts confidence to all visitors and patients, and is a much stronger drawing card than an ordinary diploma, as it indicates a higher attainment. We furnish free with each of our certificates (or at $5, when ordered separately) a solid gold lapel button of special Red Cross design in enamel and the words, 'Christian Hospital, Chicago,' in circular form around the red cross; also a neat pocket membership ticket. This alone, if displayed judiciously, will bring more dollars annually than the cost of your membership. We will agree to pay you a cash commission of 50 per cent. of all surgical fees, and 25 per cent. of all medical fees received from patients you bring or send to us. This, of course, will be held strictly private and confidential—your professional interests as well as our own demand this. It may be mentioned that the certificates of membership cost, in heavy royal linen paper, $15; imitation of parchment, $20; genuine sheep skin, $25."

The whole affair, from beginning to end, appears to be simply and solely a money-making scheme, and should for this reason alone be strongly reprobated by the medical profession. Over and above this cause for condemnation is the proposal to divide fees. It is somewhat of an unpleasant coincidence that just as the American Medical Association has promulgated new principles of ethics for the medical profession, one of the clauses of which is aimed at division of fees between medical men, expressing the strongest disapproval of such a procedure, that in Chicago, the second most important city in the country, an institution should be established, backed by several medical men of note, the main feature of which is to encourage the very practice frowned upon by the association. The project throughout is tainted with commercialism, and will assuredly convey to the lay mind no exalted view of the medical profession. It is a matter for regret that the Christian Red Cross Hospital has been established in Chicago, and it is to be devoutly hoped that its life may be a short one.

Wandering Spleen.—Heinrich Stern states that dislocation of the spleen is by no means as infrequent an occurrence as is commonly supposed. If, in every instance of absent dulness in the splenic region, the lower left segment of the abdomen would be subjected to a scrutinizing examination, the diagnosis of splenoptosis would not be so comparatively rare. However, too little attention is paid to the spleen in a physical sense and in routine practice. Providing there is no infectious disease, or no pronounced splenic affection itself, the condition or location of the spleen is hardly ever taken into account. The writer then describes the size, weight, and location of the normal spleen, and reviews the etiology and pathology of splenoptosis. He then discusses the symptoms of this condition, and its prognosis and termination. Regarding diagnosis, he states that a dislocated spleen is generally recognized without difficulty, if we bear in mind the following three diagnostic points: (1) Absence of dulness in the normal splenic area; (2) detection of a movable spleen-shaped, blunt-edged parietal tumor, with notched anterior border; (3) the possibility of pushing the movable spleen into the direction of or into its normal position.—*Medical Examiner and Practitioner.*

News of the Week.

To Restrict Consumptives.—On May 21 Governor Odell signed the Goodsell-Bedell bill prohibiting the establishment of any hospital or camp for consumptives in any town without the formal consent of the supervisors of the county and town board of the town. The Governor, in a memorandum filed with the bill, gives a somewhat disingenuous explanation of his action. On May 20 the Board of Trustees of the City Club telegraphed to Governor Odell asking him to veto the Goodsell-Bedell bill, which would prevent the establishment of a hospital for consumptives in any township without the consent of the town authorities. "The effect of the bill," said the telegram, "would undoubtedly be to compel New York City to care for its consumptives within its own limits and, therefore, under conditions not favorable to recovery of curable cases. Many lives which might be saved would thus be sacrificed. Existing laws afford all necessary safeguards for local interests."

To Beautify New York.—The Municipal Art Society has submitted to the Mayor of New York its scheme for beautifying the city. The report suggests that all important streets should have an underground railway for pedestrians that would afford relief, especially during crowded hours. It is also recommended that arcades be constructed at convenient points; that parks be laid out along the water front, and that, in different parts of the city, monuments be erected and tablets to commemorate historical events and distinguished individuals.

A Roof-garden Dormitory.—A roof-garden dormitory is to be installed at the City Hospital, Philadelphia. The idea is that of Dr. Martin, the new Director of Health and Charities, who thinks that the carrying out of such a plan will be the means of giving those suffering from tuberculosis nine hours more of each clear day in which to breathe the open air. In the daytime the cots will be removed, and the roof, with flowers and shrubbery, will be used as a promenade and recreation ground for the consumptives.

Reported Illness of King Edward.—According to the *New York Sun*, there are rather serious rumors current in regard to the health of King Edward. These stories have been in circulation for several days past. They are to the effect that he had a sudden attack of pain at the opera just after returning from France. A few days later, while he was in Scotland, His Majesty experienced similar attacks, which resulted on two occasions, it is said, in fainting spells. The King is under careful treatment and observation, but it is thought that an operation may be necessary within a short time. In the meanwhile he is able to go about. More recent reports are to the effect that the King is enjoying his usual health.

Rheumatism Cured by Bee Stings.—The sting of a bee has long been regarded by the poorer agricultural classes of Europe as a cure of rheumatism. Dr. Perc of Marburg, Germany, has recently been advocating its efficacy before a brilliant gathering of physicians, to whom he declared that he thoroughly tested the treatment and demonstrated its efficiency in 500 cases. If a bee stings a person suffering from rheumatism, the stung part does not swell, until the bee poison has been frequently introduced, when the rheumatic pain vanishes. Dr. Perc's mode of procedure is to allow his patients to be stung at first by a few bees gradually increasing the number. Dr. Perc asserts that by this treatment he has cured patients suffering from obstinate and most painful rheumatism.

Smallpox Increasing in Philipsburg.—The number of smallpox patients in Philipsburg keeps increasing. The health authorities will probably take steps soon to have a pest-house erected and to guard more effectively against persons visiting houses where the disease exists. It is said they are frequented now in spite of quarantines.—*New York Tribune*

Spitting in Public in London.—The following by-laws or regulations have been made by the Board of Trade under the powers conferred upon the Board by the London County Tramways' Act, 1896: "(1) No person shall spit in, or upon, any carriage used on any tramway worked by the London County Council. (2) Any person offending against or committing a breach of the foregoing by-law or regulation shall be liable to a penalty not exceeding £2 ($10). (3) These by-laws or regulations came into operation on April 28, 1903."

Vaccinating at Mills' Hotel, No. 1.—On account of the fact that George Francis Train was taken ill with smallpox after leaving the Mills' Hotel, Bleecker Street, his usual place of residence, a squad of Health Board vaccinators visited the hotel on Friday morning, May 22, and vaccinated every lodger on whom they could lay their hands.

Meningitis on Receiving Ship Minneapolis.—Another case of meningitis has occurred on the receiving ship *Minneapolis*. It has been decided to place the *Minneapolis* out of commission and to have her quarters thoroughly overhauled and rearranged.

Infected Army Blankets Spread Typhoid Fever in England.—"There has been," says the London correspondent of the *New York Tribune*, "a narrow escape from an outbreak of typhoid fever in London and thirty or more industrial centers from the sale and distribution of army blankets from the fever hospitals in South Africa. The danger has only been averted by the energy and vigilance of the sanitary authorities. The public indignation is intense, especially as the medical experts have discovered the army blankets warehoused, blood-stained, and infected with typhoid bacilli. These blankets were sold in South Africa by the authority of the War Office, after the close of hostilities, and apparently there was incredible carelessness in neglecting to classify the superfluous army stores, disinfect all the goods, and destroy those used in the fever hospitals. The indiscriminate sale, shipment and distribution of 150,000 of these blankets constitute a military scandal which is almost without precedent, and closely approaches criminality.

Beds Endowed at Roosevelt Hospital in Honor of Dr. Jacobi.—Four beds at the Roosevelt Hospital have been endowed in honor of Dr. Abraham Jacobi, until last year the professor of children's diseases at the College of Physicians and Surgeons.

Hospital Privileges for Homeopaths.—Philadelphia Councils' Committee on Charities and Correction has approved an ordinance authorizing the Director of the Department of Public Health to establish five wards in the Philadelphia Hospital for homeopathic treatment—namely, a men's surgical, a women's surgical, a men's medical, a women's medical, and a medical and surgical ward for children.

Philadelphia Academy of Surgery.—At a stated meeting, held May 11, Dr. W. J. Mayo of Rochester, Minn., read a paper entitled "A Review of Three Hundred and Three Operations upon the Stomach and the First Part of the Duodenum." The discussion was participated in by Dr. Albert Vander Veer, Mr. G. A. Moynihan, Dr. John B. Murphy,

Dr. J. M. T. Finney, Professor Mikulicz, and Dr. J. Chalmers Da Costa.

Philadelphia Pediatric Society.—At a stated meeting, held May 12, Dr. Augusta A. Eshner exhibited a patient with probable rachitic deformity. There was present enlargement of some of the metacarpal bones and the phalanges of the hands, with a prominent forehead and notched teeth. A sister of this patient, who was likewise presented, exhibited mental deficiency, with fulness of the cheeks and an appearance suggestive of cretinism. Each child improved under treatment, the one with potassium idodide, the other with thyroid extract. It was thought that the condition in each might be due to some common cause, some vice in heredity of the ancestry, perhaps syphilis, capable of causing nutritional and structural disturbance in the offspring. Dr. John H. Gibbon exhibited a patient with perineal ectopic testicle. The infant had been brought on account of the belief on the part of the parent that a hernia existed, but examination disclosed the presence of the testicle in the perineum. Operation was advised and performed, the displaced organ restored to its normal position and fixed by sutures. Dr. Gibbon also reported a case of peritonitis due to a strangulated Meckel's diverticulum and he exhibited the specimen. Dr. Eshner exhibited a patient with mitral obstruction characterized by a marked thrill and a typical presystolic murmur followed by a systolic shock. Dr. C. F. Judson reported a case of severe chorea complicated by pneumonia. Drs. E. M. L'Engle and J. Woods Price reported a fatal case of oil of gaultheria poisoning in a child of two years. Dr. R. S. McCombs read "A Report of Three Cases of Aphasia."

The Camden County (N. J.) Medical Society held its annual meeting on May 12 and elected the following officers: *President*, Dr. John W. Marcy; *Vice-President*, Dr. Joseph H. Wills; *Secretary*, Dr. Paul Mecray; *Treasurer*, Dr. Joel F. Fithian; *Historian*, Dr. Alfred Cramer; *Reporter*, Dr. W. S. Bray.

Obituary Notes.—Dr. Thomas George Morton, the well-known surgeon of Philadelphia, died in that city on May 20 from cholera morbus complicated with gout, after an illness of two days. Dr. Morton was born in Philadelphia on August 8, 1835, and was the son of Samuel George Morton, a distinguished physician in his day. The deceased was graduated from the University of Pennsylvania with a medical degree in 1856. For the three following years he practised surgery in Philadelphia, and at the commencement of the Civil War displayed great energy in establishing military hospitals. He was surgeon at Satterlee Hospital and consulting surgeon to the United States Hospital at Chestnut Hill, Pennsylvania. He was the founder of the Philadelphia Orthopedic Hospital, and in 1876 was appointed commissioner to erect a State insane asylum for the Southern District of Pennsylvania. He was President of the Pennsylvania Society for the Restriction of Vivisection in 1880, and Vice-President of the Society for the Prevention of Cruelty to Children in the same year. In 1883 he was a Commissioner of Public Charities and Chairman of the Lunacy Commission in 1886. The late Dr. Morton published papers in the *American Journal of Medical Science* and "The Pennsylvania Hospital Reports," and also wrote extensively on the transfusion of blood and its practical application. He was a member of several foreign medical and scientific societies.

Dr. Edmund Charles Wendt.—Dr. E. C. Wendt, formerly of this city, during an attack of temporary aberration of mind, committed suicide by a pistol shot, on May 25, at his residence in the Rue Christophe-Colomb, Paris. He was born in Milwaukee in 1857, and was graduated from the Medical College of Strasburg in 1877, and from the College of Physicians and Surgeons three years later. After a year's connection with the German Hospital in this city, he became associated in practice with Dr. Leonard Weber. In 1886 he married Augusta Einstein, the daughter of Lewis Einstein, and began four years later to practise alone at 118 West Seventy-ninth street. He went abroad with his family in 1897, with the idea of post-graduate study. He was previously on the editorial staff of the Medical Record, and while abroad continued to be a contributor to it up to 1900. He was also the author of a work on Asiatic cholera, published by William Wood & Co., in 1885. He was much interested in sanitation, and contributed many valuable articles on the subject, the most notable of which was one on the sanitary aspects of the Reviera. He leaves a widow and two sons. Dr. Wendt was a member of the N. Y. Pathological Society and the German Medical Society.

Dr. Octavius A. White died on May 25 at his home, 1,011 Madison avenue, in the seventy-eighth year of his age. Dr. White was born in Charleston, S. C., on February 8, 1826. He graduated from the College of Charleston in 1846, and in Medicine from the South Carolina Medical College in 1848. He practised with success until the outbreak of the civil war, when he became a surgeon in the Confederate Army. While in the army Dr. White was sent into the Union lines to treat Northern soldiers suffering from yellow fever, and gained much fame as an expert on that disease. When the war was over he came to New York, where he lived until his death. Dr. White was a member of the New York Academy of Medicine, and of many other medical societies. He was a contemporary and associate of J Marion Sims and T. G. Thomas.

Prof. Thompson Jay Hudson, author of a number of psychological works and a lecturer on psychology, died from angina pectoris on May 26, in Detroit.

A Note on the Danger of Delay in the Case of Large Abdominal Tumors.—Bedford Fenwick reports two contrasting cases; the first was that of a patient, fifty-four years old, who for eighteen years had noticed a gradual enlargement of her abdomen. There was found a fibroid tumor of the uterus, part of which completely filled the pelvis, whilst it also extended upward to the ensiform cartilage and distended the abdomen. The cardiac sounds and action were extremely feeble; the patient also suffered from attacks of great dyspnœa. She pleaded for operative relief, although warned of its dangers; two large and almost separate masses were removed, and the patient recovered from the operation. On the tenth day she suddenly died, and at the post-mortem it was found that while the abdomen and pelvis were perfectly healthy, the heart was the seat of extensive fatty degeneration, the thickness of the wall of the ventricle being only about that of a sheet of blotting paper. The second case was similar in so far as the size of the fibroid tumor was concerned, but in this case the mass had grown within the last year, the patient was forty-four years old, and the heart's action and sounds were fairly normal. The operation was more difficult than in the former case, because the fibroid was degenerated, and there were extensive adhesions to the intestines and to the pelvic floor. The patient, however, recovered rapidly and without a single bad symptom. These cases illustrate what the author has long insisted upon, that fatty degeneration of the heart is caused by long-continued upward pressure on the part of abdominal tumors. —*The Medical Times and Hospital Gazette.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL AFFAIRS IN THE LONDON, BART'S, MIDDLESEX, EAST LONDON, CHILDREN'S, NATIONAL FOR EPILEPSY—DISCUSSION ON RECTAL CANCER—SIR WILLIAM GAIRDNER—ANTIVIVISECTIONISTS—PARLIAMENT; VACCINATION AND SMALLPOX.

LONDON, May 8, 1903.

THERE was a large and distinguished company at the great dinner given by the Lord Mayor on Monday in aid of the London Hospital. In giving the loyal toasts, his Lordship remarked, on the eve of the King's return from a journey which will have a beneficent influence, that his majesty is the most popular gentleman in Europe at the present time. Like the King, the Queen has ever taken the most lively interest in hospitals, as also does every member of the Royal family.

In giving the toast of the London Hospital, the Lord Mayor said it was both the largest and the poorest hospital in England, and situated in the poorest part of London. Seven hundred patients slept there every night, and with the staff 1,000 souls were housed within its walls. The annual expenditure was £90,000, the assured income only £22,000. A gift of £1,000 would endow a bed, £500 a child's cot. He hoped donors would be found to endow all the beds in one ward as a commemoration of the approaching visit of the King and Queen. The Duke of Cambridge replied as president of the hospital, and Sir F. Treves for the staff. The Lord Mayor then announced that £127,000 had been received out of the half million required.

Mr. Sidney Holland, chairman of the committee, proposing the health of the Lord Mayor, said the Lady Mayoress had given £1,000. The Queen had given £1,000 with two more Finsen lamps and expensive adjustments to the others. The managers had to face an expenditure on necessary alterations of £170,000, and a yearly deficit of £20,000. In five years, at this rate, they would have no more investments to meet this annual deficit.

I wish his appeal to rich men for funds success, but cannot ignore the fact that too much money has been expended on the out-patient department.

On Tuesday the Lord Mayor presided at a meeting of the Committee of Inquiry in the affairs of St. Bartholomew's Hospital. The report of the sub-committee on the financial and administrative management of the hospital was read. After a lengthened consideration of this report the committee adopted a resolution declaring "that the governors have completely vindicated the reputation, character, and administration of the hospital, and are fully justified in appealing to the public for funds to enable them to utilize the land acquired from Christ's Hospital, and to provide the new buildings urgently necessary to bring the hospital up to modern requirements in all respects."

The Middlesex Hospital has erected a galvanized iron building for the installation of the Finsen light, the *x*-rays, and high-frequency treatment of cancer. When a site and funds are forthcoming, the managers hope to erect a permanent building for this purpose, provided the work carried on in the temporary structure justifies the further outlay.

The annual dinner of the East London Hospital for children was held on Monday, when subscriptions to the amount of £1,705 were announced. The hospital is situated in a very poor locality, has only £1,000 of assured income, but needs ten times as much to meet the continually increasing demands made upon it.

The National Hospital for Paralysis and Epilepsy also wants to enlarge its boundaries now that harmony is restored in its management. Its income is only £10,000, its expenditure £18,000, and it wants £25,000 for new buildings. At the dinner on the 30th ult., £1,882 was the amount raised. Sir W. Gowers congratulated the hospital that its pathologist, Dr. F. Burrard had discovered the organism of acute ascending paralysis.

Rectal cancer was the subject of a discussion at the Medical Society on the 27th ult. The debate was opened by Mr. Watson Cheyne, who held that excision was a valuable method of treatment in suitable cases, some patients remaining free from disease for a long time after the operation. The chief points for consideration were the mobility of the portion affected, the presence or signs of the disease elsewhere, and the patient's general condition. In unsuitable cases colotomy was not required at an early period, for some patients could go on to the end without it. Therefore it need not be done unless special reasons called for it, *e. g.*, tight constriction threatening obstruction, communication with the bladder, urethra, or vagina, intense tenesmus and irritability of the rectum. In excising the rectum, preliminary colotomy was only rarely required, but measures for obtaining asepsis, such as prophylactic injections of antistreptococcic serum, disinfection of perineum, and occlusion of anus were advised. Union of the ends of the bowels should be aimed at, provided the upper end could be drawn down into the lower end for at least half an inch. If this seems inadvisable, the bowel at the point of attachment to the skin should be firmly ligatured, so as to prevent the exit of fæces for three or four days. As an alternative, a Paul's tube might be tied in. Gersuny's half or three-quarter turn of the bowel was of value; it diminished subsequent incontinence.

Mr. Waterhouse submitted that excision of the neoplasm and removal of the glands which would be the first affected should be done whenever practicable. Preliminary colotomy was never necessary, but in cases unsuitable for radical treatment was often invaluable, as for obstruction or intense pain on defecation; it should be postponed as long as possible. In quite half the cases the time for radical operation was passed before the surgeon saw the patients. Mobility of the growth indicated and immobility contraindicated excision. The mortality of excision he reckoned at about 18 per cent. The majority of patients were greatly benefited. The facility with which the rectum could be drawn down toward the anus when the reflection of the peritoneum was simply divided astonished those who saw the procedure for the first time. The crux was the treatment of the divided ends. The ideal method consisted in shelling out the mucous membrane of the anal segment and stitching the lower end of the upper one to the anal margins, thus preserving the sphincters intact. Union of the ends should always be attempted, and would generally succeed, at any rate in part. No tension is permissible or the sutures would certainly cut out. Union by first intention might often be attained in the upper three-quarters of the incision.

Mr. Goodsall disagreed with the previous papers as to colotomy, which he held should be done as early as possible. The disease had usually existed some nine months before the patient saw the surgeon, and then the bearing-down pain and frequent action of the bowels were distressing. Colotomy relieved these symptoms. He advocated its performance, and three weeks later radical removal when practicable.

Mr. Wallis urged the importance of early diagnosis. Rectal examination should be made in all cases of obscure diarrhœa and tenesmus. In young patients the growth was so rapid that removal soon became impracticable. An anæsthetic should be used, for under it a growth would sometimes be found movable, although without it this was not so. A stream of hazeline and water playing over the wound during the operation seemed to him to aid in preventing infection.

Mr. Barker doubted whether resection did more for the patient than colotomy. Some of his colotomy patients had survived eight or nine years. The best results of excision gave a mortality of 5 per cent., and only about 25 per cent. had complete control over the evacuations.

The President (Mr. Pearce Gould) commented on the differences of opinion expressed. He asked himself in each new case—is this suitable for excision? If so, it should be done, for it often permanently relieved. Colotomy often restrained hemorrhage, but less certainly relieved pain. In some cases arrest of further growth seemed to follow colotomy.

Mr. Cheyne, in reply, said he did not condemn colotomy entirely, but would not propose it early; as long as a patient was comfortable he was better without it.

Mr. Waterhouse also replied. He found colotomy seldom relieved the sacral pain. It was urgently called for when hemorrhage was serious.

Sir William T. Gairdner, K.C.B., has had the degree of LL.D. conferred upon him by the University of Glasgow, in which he was for so long professor of medicine. At the same time this degree was conferred on Prof. Thos. Oliver, M.A., M.D.

A little book has just been published by Sir William Gairdner, entitled "The Three Things that Abide." It consists of addresses on faith, hope, and love, delivered on Sunday evenings in connection with a series of discourses by others. To these is added one specially addressed to the White Cross Society of Edinburgh University. An appendix on the words expressing love in Biblical Greek and in the Latin, German and English versions is very interesting.

The antivivisectionists assembled in strength the other night to celebrate the twenty-ninth annual meeting of the society, of which Mr. Stephen Coleridge, barrister-at-law, is the secretary. Three peers, several peeresses, a bishop, an admiral, an author or two, and many ladies were present. Lord Llangattock presided and said he

came to testify against what was displeasing to God. He is the lord whose battue of pheasants was exposed on a former occasion. Lord Ernest Hamilton said that in the middle ages the priests exercised a despotism founded on ignorance and superstition; but in the present day the doctors exercised a despotism based on cruelty and superstition. This was too much for Bishop Bargshawe, who forthwith protested against the statement about priests, and declared his firm conviction that poor patients were experimented on in the hospitals to gratify scientific curiosity.

Sir F. Banbury, M.P., declared he would sooner die than permit animals to be treated on the half chance that something useful might be discovered.

These are samples of the statements made by the speakers. One more will show the accuracy of these antis. It was that in nine hundred and ninety-nine cases out of a thousand there was not the slightest intention or desire to benefit mankind by experiments on animals. This assertion was received with cheers, which will illustrate the antis' love of exact truth.

In reply to questions in the House of Commons last night it was stated that the use of human lymph by public vaccinations was discontinued at the beginning of 1899. The change was made on the recommendation of the royal commission on vaccination. It was further stated that 799,092 tubes of glycerinated calf lymph were issued during the financial year of 1902-3.

Smallpox continues to spread in several localities, chiefly in the northern and midland counties. In Liverpool it is said that 1,400 cases have occurred during the last six months with ninety deaths, and a question is to be asked in the House about it, suggesting inquiry by a government inspector.

HYDROPHOBIA RUN TO EARTH.

To the Editor of the Medical Record:

Sir: It is strange that those who would have us to believe that hydrophobia is a common disease continue to present such meagre histories of reported cases, with the advent of summer there will doubtless come this year as herctofore, what amounts to but hearsay reports of rabies in humankind.

I desire to direct attention to some points for comparison between tetanus and hydrophobia as commonly set down in medical works, tetanus undoubtedly being the true cause of death in the majority of instances. (1) Incubation of tetanus extending up to a period of from three to five weeks; in hydrophobia six weeks is given as a short period of incubation. (2) In tetanus rigidity of muscles of neck, throat, and lower jaw are the earliest manifestations; in hydrophobia clonic convulsive seizures, involving especially the throat muscles. (3) In tetanus close mind with absence or mild fever until near the close; in hydrophobia excess of temperature is not dwelt upon or is moderate, delirium at the close. (4) In tetanus post-mortem examination has demonstrated congestion of the spinal cord and peripheral nerves. The cord after death from hydrophobia is found intensely congested also respiratory mucous membrane. (5) Inoculation with rabies is said to be invariably fatal, yet only 12 to 14 per cent. of those bitten by rabid animals die (Roux); tetanus can show an equal if not a greater mortality. Lastly, the part which fright plays in mania production of hydrophobia must be differentiated.

Most writers upon the subject of the life history of the tetanus bacillus mention garden earth, dust, and manure as its constant habitat, and are seemingly impressed not only with its general distribution throughout temperate and tropical climates but with the tenacity of its life as well.

Dogs and hydrophobia are synonomously suggestive terms—the relation of dogs as a common carrier of the tetanus germ may be proven by axiomatic demonstration.

The wayfaring canine, as well as the leash-led pavement traveler, when out of sorts instinctively seeks medication. As a "sick dog hunts for grass," so will these ailing ones, starved and thirsty or pampered and overfed, seek grass even at second hand, or, in other words, will loll and consume street manure. By this means does the tetanus germ gain access to the saliva of the animal and a media for propagation is provided. The hooting crowd to the tormented cur or the teasing of milady's poodle supply the remaining factor in the chase.

The common method of emergency treatment for dog-bites carried out by the druggist and ambulance doctor alike, namely, cauterization with lunar caustic, is mentioned to be condemned. Injection of hydrogen dioxide, in full strength, into such wounds when first seen would act as an antidote to pus as well as the more virulent tetanus germ.

Progress of Medical Science.

The Boston Medical and Surgical Journal, May 21, 1903.

The Germicidal Action of Alcohol.—Charles Harrington and Harold Walker conclude from their investigations that: (1) Against dry bacteria, absolute alcohol and ordinary commercial alcohol are wholly devoid of bactericidal power, even with twenty-four hours direct contact, and other preparations of alcohol containing more than 70 per cent. by volume are weak in this regard, according to their contents of alcohol—the stronger the alcohol, the weaker the action. (2) Against the commoner non-sporing pathogenic bacteria in a moist condition, any strength of alcohol above 40 per cent. by volume is effective within five minutes, and certain preparasions within one minute. (3) Alcohol of less than 40 per cent. strength is too slow in action or too uncertain in results against pathogenic bacteria, whether moist or dry. (4) The most effective dilutions of alcohol against the strongly resistant (non-sporing) bacteria, such as the pus organism, in the dry state, are those containing from 60 to 70 per cent. by volume, which strengths are equally efficient against the same organisms in a moist condition. (5) Unless the bacterial envelope contains a certain amount of moisture, it is impervious to strong alcohol; but dried bacteria, when brought into contact with dilute alcohol containing from 30 to 60 per cent. of water by volume, will absorb the necessary amount of water therefrom very quickly, and then the alcohol itself can reach the cell protoplasm and destroy it. (6) The stronger preparations of alcohol possess no advantage over 60 to 70-per cent. preparations, even when the bacteria are moist; therefore, and since they are inert against dry bacteria, they should not be employed at all as a means of securing an aseptic condition of the skin. (7) Provided the skin bacteria in the deeper parts can be brought into contact with disinfectants, alcohol of 60 to 70 per cent. strength may be depended upon usually, but not always, to destroy them within five minutes.

Journal of the American Medical Association, May 23, 1903.

The Stegomyia and Fomites.—S. E. Chaille reviews the experiments of recent years as to the etiology of yellow fever and arrives at the following conclusions: The probabilities now are that the stegomyia, the only cause yet proven, is the sole cause for the dissemination of yellow fever; but that time is required to convert these probabilities into certainty. Boards of health, should they neglect any practicable measure of warfare against the stegomyia, would deserve the severest punishment of the worst criminals. Southern boards of health are excusable for over-precaution against yellow fever. States adjacent to Louisiana have power, by sanitary restrictions, to strangle the commerce of New Orleans, and Louisiana should not abandon the disinfection of fomites until approved by said States. Boards of health are representatives of the people and are justified in continuing to disinfect fomites as long as public opinion may favor this measure and until the probability of its inutility is converted into certainty.

Contribution to the Surgery of Gastric Ulcer.—Van Buren Knott offers the following conclusions: (1) Perigastric adhesions as sequelæ of chronic ulcer of the stomach are not uncommon. (2) Their existence should be suspected and even positively diagnosed more frequently than has been the case. (3) In many such cases the relief afforded by the operation is absolute and may be secured in no other manner. (4) The operation is often an extremely simple one. (5) If the adhesion involves surfaces so extensive that its recurrence must be inevitable, relief may be best secured by a gastroenterostomy allowing the adhesions to remain. (6) The use of omental grafts or Cargile membrane is of value in preventing the readhesion of the separated surfaces.

The Serum Diagnosis of Tuberculosis.—L. M. Loeb details his experimental experience and lays down the following propositions: (1) Under various conditions animal sera agglutinate homogeneous cultures of human tubercle bacilli in liquid media. (2) Such sera may be obtained from the human or animal body without the presence in it of the bacillus tuberculosis. (3) It is doubtful whether the agglutinative powers are ever due to the specific action of the bacillus tuberculosis. (4) The presence or absence in the adult human blood serum of agglutinative properties for tubercle bacilli is no decisive evidence of the presence or absence of tuberculous lesions in the body.

New York Medical Journal, May 23, 1903.

Atony of the Duodenum Diagnosticated and Corroborated by Operation.—M. I. Knapp reports the case of a patient, a woman aged forty-four years suspected to have intestinal carcinoma. Operation revealed an intestinal stricture due

to a fusiform tumor involving all the bowel coats; microscopical examination of the mass showed it to be of an inflammatory nature and not malignant. Fifteen inches of bowel, including the tumor, were removed, and the patient made a good recovery. She is now well, nine months after operation. The author states that a tumor in a middle-aged person, coexistent with pain and emaciation, need not necessarily be cancer. The pain in this case was evidently not due to the tumor, but to distention and colic produced by the same agencies as usually do produce colics. As soon as the bowel was cleared of offensive material the patient felt fully well. Much stress is laid upon the intermittency of the patient's pain. Cancer pain is constant.

Eclampsia: Its Prevention and Treatment.—E. A. Ayres discusses the question suggested by the title of his paper and summarizes his personal experience in the statement that he has seen forty-six cases, four of which died. Several patients recovered whom he expected to die; and one died after both her physician and himself considered her fairly out of danger. It is his belief that he has prevented eclampsia in fully a score of cases, though one can never be certain how to classify such cases. He has employed nitroglycerin in all cases; chloral, chloroform, and veratrum viride variously according to indications; dry and moist hot packs; saline infusion and injection; and various methods of cervical dilatation.

Medical News, May 23, 1903.

The Circulation in Puerperal Elcampsia.—Douglas H. Stewart states that the whole arterial system presents a picture of over-stimulation and of force and resistance to force. If the blood quantity is increased, quality is lowered and poisons are augmented beyond any protective destruction which the liver affords against the toxic conditions within the portal vein of even the healthiest animal. Plethoro-toxæmia would about describe the condition. In eclampsia the left ventricle is hypertrophied, and the law of rapidity inversely as power is violated. The pressure on the arterial side is more than 10 to 1 on the venous. The veins are so underfilled that contractions of pulmonary and vena cava aid the blood into the auricle over the area of negative tension. The vasomotor center will restore and maintain the normal, despite any local fall of tension, and blood-pressure cannot be reduced short of dangerous hemorrhage and collapse. This pressure falls after venesection, because poison is withdrawn and not because blood is drawn. To diminish arterial tension one should bleed from an artery, not from a vein. As the thorax aspirates the venous, so it drives the arterial flow, and as the arterial circulation is already overfilled, in puerperal eclampsia, calm respiration is decidedly desirable.

Some Interesting Phenomena of Specific Immune Sera.—Arthur P. Hitchens says that in an article by Richardson the union and relations between complement, immune body, and corpuscle or bacillus are represented in a very diagrammatic manner. At the height of the disease, in the few cases investigated, there was not only no active complement in the blood of the patient, but the serum contained something which united with complement from without—probably a neutralization by or union with the immune body. Added, however, in the bacillus and typhoid and normal order, the bacillus was united by its receptor to the immune body in the typhoid serum, allowing the complement to act as the alexin. Researches on the subject of cytolysins justify the deduction that the bodily capacities at work in hæmolysis are identical with those concerned in bacteriolysis and bactericidal action, but while the processes are the same, it does not follow that the substances which cause hæmolysis are identical with those which give rise to bacteriolysis. The writer believes that we are approaching an accurate knowledge of the phenomena concerned in immunity.

Rheumatic Tonsillitis in Children.—John Stewart has many times seen diphtheria and pharyngitis taken for tonsillitis. In the latter affection the yellowish-white spots can be removed from the crypts and will disappear in two days. Calomel and salines are first in the treatment of this disease. Salicylic acid or sodii salicylate acts as a specific when given internally in small doses. If given from the outset, this will often prevent suppuration, shorten the attack, and relieve the pain and swelling. Tr. guaiac ammon., if given in hot milk as a gargle, will often abort an attack, and if the case has advanced to about the fifth or sixth day, it will give almost immediate relief. H_2O_2, 25-per-cent. solution, as a swab, will, if continued through the case, afford great relief. The writer does not use Tr. ferric chlor. until convalescence. The diet should be in the shape of gruels, etc. Ice pellets give relief. At times it seems as though nothing gives any relief, and at the end of seven days all symptoms of inflammation subside at once.

Philadelphia Medical Journal, May 23, 1903.

The Present Treatment of Puerperal Septic Infection.—Edward P. Davis speaks of the methods of treatment which have proven of value in this affection. Upon the development of septic infection, the uterus and vagina should be cleansed as thoroughly as possible; foci of infection, when accessible, should be destroyed; ulcers upon the vulva and vagina should be cauterized with carbolic acid and iodine, or with any other suitable strong antiseptic. The vagina should be thoroughly sponged out with cotton dipped in lysol, 1 per cent., or mercury bichloride, 1-4000; the cervix should be inspected and ulcers cauterized and disinfected; the uterine cavity should be explored gently by a blunt-edged curette and its interior gently, but thoroughly, scraped, to bring away necrotic material. This exploration may be accompanied by prolonged irrigation, with lysol or creolin, 1 per cent., or normal salt-solution. If bleeding is excited, it is well to pack the uterus moderately with gauze containing 10 per cent. of iodoform. The vagina should be lightly tamponed with dry bichloride gauze, which should not be disturbed for forty-eight hours. At the end of this time, the uterus and vagina should be thoroughly irrigated with lysol, 1 per cent.; no further douching of any kind should be practised. The application of cold to the abdomen over the uterus is of decided value. The prompt and thorough emptying of the intestines is of great importance. Medication should be limited to the use of those drugs which act most efficiently as tonics and stimulants to the nervous system and which produce contraction of the uterus; strychnine and ergot are most valuable. All septic patients must be liberally fed; good nursing is most valuable.

A Fatal Case of Anthracosis, with Autopsy.—Thomas Stotesbury Githens describes this case. The patient was a man twenty-seven years of age. His occupation was that of barber, and he gave the history of syphilitic infection five years before. This present illness had lasted several years; it had started with dyspnœa and cough, with a sligh pain in the side at times; he had had night sweats for the past year, but there had been no blood in his sputum. Tubercle bacilli were not found, and the amount of pigment was not sufficient to excite remark. A diagnosis of tuberculosis was made in spite of the fact that the examination of the sputum was negative. At autopsy no tubercles could be found; the peribronchial and mediastinal glands were large and black. The lungs were intensely pigmented with coal dust and extensively fibrous. Microscopically the pigment granules were, in part, extra-cellular, in part enclosed in cells.

Upon the Local Use of Cocaine in the Nose.—William G. B. Harland says that the usual dangers of cocaine in the nose are as follows: drug habit, secondary congestion and hemorrhage, local subjective sensation, and effects attributed to the so-called idiosyncrasy. The drug habit is terrible in its results, and is practically incurable. Hemorrhage, if it occurs, will, of course, be in proportion to the amount of congestion present; iodoform gauze or similar packing makes a satisfactory guard against this important complication. In some persons the sensation of constriction and strangulation is induced if even a small amount of cocaine reaches the rhinopharynx and pharynx. Just how cocaine produces the alarming faintness and other symptoms which sometimes arise has not as yet been explained. Adrenalin chloride has proved a most valuable aid in lessening the dangers and in enhancing the powers of cocaine.

American Medicine, May 23, 1903.

Anomalies of Respiration in High Altitudes.—W. A. Briggs reports several cases. One patient in lying down on the mountain side, after a morning climb, would often drop into a doze, and then in a few moments awake with precordial distress and labored breathing. This would cease in a moment and the breathing become superficial. Another patient, who had a slight "cold," complained severely of nasal obstruction, particularly when recumbent, and of frequent sighing. In another patient, a double cardiac sound developed. The exciting cause of these anomalies would seem to be dependent upon high altitude. The genetic chain would seem as follows: diminished supply of oxygen under diminished pressure; oxygen hunger; increased activity of the respiratory apparatus; exhaustion of the respiratory muscles and center; irregular respiratory impulse. In some cases obstruction of the air passages may be contributory.

Retrocæcal Appendicitis with Retroperitoneal Pelvic Abscess.—A. Ernest Gallant states that he has operated on quite a number of patients in whom the appendix was found lying behind the cæcum, with an accumulation of pus and exudate around and under the caput coli, but in only the three cases here reported have the abscesses been

located in the pelvis behind the peritoneum. This variety of appendicular disease (retrocæcal) has been characterized by the usual acute onset, with nausea, vomiting, malaise, general abdominal pain, which later becomes localized in the right iliac fossa, unequal abdominal rigidity, constipation, and moderate elevation of the temperature and pulse. Tumefaction in the right iliac fossa can be recognized, and on examination per vaginum or rectum, the pelvic abscess, when present, can be easily made out.

The Lancet, May 16, 1903.

The Use of Pilocarpin in the Treatment of Pneumonia.—The histories of seven cases are given by E. Curtin. He states that the remedy relieves the pain and breathing within a few hours of its administration and also seems to hasten resolution, probably by exciting glandular secretion. Its administration is, in the majority of cases, followed by a rise of temperature of from half a degree to one and a half degrees. One-tenth of a grain hypodermically does not cause profuse perspiration, but rarely fails to reduce the temperature within an hour or two. It also cleans the tongue and stimulates the flow of saliva. Curtin has not noticed its repeated administration attended by any undesirable or unpleasant results. One precaution is necessary—namely, to keep the patient warm, and especially the feet.

Abdominal Hysterectomy for Myoma by Doyen's Procedures.—W. G. Spencer alludes to the Doyen method, which consists essentially of a rapid division of the structures between clamp forceps, the cutting down of a posterior flap into the vagina, the grasp and elevation of the the cervix and the turning of the tumor gradually over the pubes by a sort of somersault movement. He gives details of eight cases treated by this method, the points in favor of which he enumerates as follows: (1) the certainty of the procedure in spite of inflammatory complications or the main tumor obscuring details; (2) the certainty of securing the uterine artery at a good distance from its origin; and (3) the ease with which the bladder and ureters are pushed out of the way of the field of operation.

Methylene Blue in the Treatment of Malignant Malarial Fever.—Commenting on the fact that quinine has practically no effect on the crescent bodies met with in malignant malarial fever, J. M. Atkinson narrates the case of a Chinese boy, aged fifteen years, suffering with the disease in question. Quinine was given for a week, but without avail. Two grains of methylene blue were then administered in pill form three times daily. After a week no more of the crescentic bodies were found and the patient made a speedy recovery. After a week's usage of the methylene blue, symptoms of gastric disturbance came on, but they quickly ceased upon the withholding of the remedy.

British Medical Journal, May 16, 1903.

Hodgkin's Disease and Arsenical Poisoning.—Walter Broadbent reports an interesting case of Hodgkin's disease in a person peculiarly susceptible to arsenic. The patient was a woman aged 58; the occipital, cervical, subclavicular, inguinal, abdominal and pelvic glands were enlarged. They varied in size from a pea to a chestnut. They were all quite distinct and rather firm and hard. She also had slight œdema of the feet. Hodgkin's disease was diagnosed, and liq. arsenicalis ♏ v t. d. At the end of a fortnight she felt much better, was less short of breath, with no œdema of the feet and a distinct diminution in the size of the glands. She complained, however, of a burning pain in the soles of her feet, and had a slight purpuric rash on her shins. In consequence, the arsenic was stopped, but there came on keratosis of the soles and slightly of the hands, followed by desquamation, increased pigmentation of the skin, and four weeks after the stopping of the arsenic, a severe attack of herpes of the right side of the neck. This was succeeded by most intense and persistent neuralgia, which resisted all treatment. During this time the glands all rapidly decreased in size, and in two and a half months had almost disappeared, but then began to enlarge again. Under phosphorus there seemed no increase of the glands for three weeks, but they then began to enlarge rapidly; nothing delayed the disease except arsenic. Sodium cacodylate was begun, but was followed after a time, by a trace of albumin in the urine, so this medication was discontinued. An acute attack of pleurisy started on the leftside, fluid was aspirated, and she seemed to be making progress for a time, but the swelling of the glands began to return, and she finally developed great irritability of the stomach, which resulted in her death, from exhaustion. The author attributes the pleural effusion ascites and œdema to the sodium cacodylate. In other diseases usually treated with arsenic one may also meet with possible signs of poisoning.

Case of Chlorodyne Poisoning, with Recovery.—K. R. Dalal reports this case. The patient was a Parsee lad aged eighteen. He was found one morning lying unconscious in his bed, drenched with profuse perspiration. The whole body was quite cold to the touch, the pulse imperceptible at the wrist and the breathing embarrassed, the respirations being shallow and quick. On auscultation, the heart sounds were found to be very feeble and fluttering without any rhythm, and the heart's impulse was quite visible about an inch outside of the left nipple line. Ether and tincture of digitalis were injected over the cardiac region. Mustard plasters were applied to the nape of the neck and over the cardiac region, and also hot fomentations were applied all over the body. The pupils were equal, regular, and in a state of moderate contraction, and they responded well to light. The tongue was dry and appeared white and shrivelled, as if some acid had been taken. Ether and digitalis were again injected, as the heart sounds had become so weak that it was feared they would come to a standstill. Hot coffee was injected per rectum; the pulse became much better; another injection of coffee with two ounces of brandy was given and soon after the patient became a little conscious. The patient's appearance suggested that he had taken some narcotic drug. Rectal injections of coffee were continued and he was flapped on his face with wet towels. As he became quite conscious, aromatic spirits of ammonia was administered with a little water to drink, a few minutes after which he vomited, but no odor of any drug could be detected. He was now practically out of danger. It was discovered that he had taken two drachms and a half of chlorodyne.

Case of Acute Alcoholic Poisoning in a Child Aged Four Years; Treatment by Saline Injection; Recovery.—Frederick C. Forster relates this case. The patient was a boy of four years, who drank two ounces of strong neat whiskey. It was taken about eight in the morning on an empty stomach. A hypodermic injection of strychnine sulphate was given and the stomach was siphoned; the child being insensible at the time. He was then wrapped in blankets, with hot bottles around him, and cloths constantly wrung out in hot water placed on the chest, but was as deeply comatose as before and seemingly dying from shock. Again strychnine and digatilin were given, and the child placed in a tub of hot water and vigorously rubbed. There was scarcely any improvement. Warm saline solution per rectum was administered and the patient slowly rallied from his collapse, so that in about half an hour he was able to take some hot beef tea; from this stage his recovery was rapid.

Deutsche medicinische Wochenschrift, April 30, 1903.

Presence of Specific Substances in the Bodies of Bacteria.—L. Briegeri and M. Mayer, by a special method, have extracted from the bodies of typhoid bacilli, a substance which, when inoculated intravenously into rabbits, gives rise to a serum which agglutinates typhoid bacilli in high dilution (1 to 1,200 to 1 to 2,000). This agglutinating power appears very quickly after such inoculations and soon reaches its maximum. It then quite rapidly descends, and cannot be accentuated by repeated inoculations. This latter is in contradistinction to the immunization produced by the inoculation of the bacterial bodies themselves. Bactericidal bodies or precipitins are not produced by the inoculations above described, and intraperitoneal inoculation shows that these extracted substances do not possess any toxic properties.

Paratyphoid Fever.—Heinrich Kayser reports three cases. The diagnosis was made on the basis of a specific agglutination in high dilution (1 to 100 and 1 to 1,000) of Schottmüller's paratyphoid bacillus (type B.) by the blood serum of the patient. In one of the cases an agglutination was also given with the typhoid bacillus in a 1 to 50 dilution, but since it could not be produced in higher dilution, and at the same time an agglutination was obtained with the paratyphoid in a 1 to 1,000 dilution, the former reaction is to be regarded as one of the "group" agglutinations which are frequently observed. In all of the cases a typical typhoid roseola was observed. All recovered.

Berliner klinische Wochenschrift, May 4, 1903.

Traumatic Tuberculous Peritonitis with Appendicitis.—R. Lücke's patient was a boy of twelve years of age. His previous personal and family history was excellent. He received a fall while skating and immediately experienced intense abdominal pain. Within twenty-four hours the classical symptoms of diffuse peritonitis with appendicitis developed. The severity of the symptoms subsiding, operation was delayed for fifteen days when it was undertaken, the patient dying in collapse two hours thereafter. The operation showed the appendicitis and the tuberculous peritonitis. A careful hunt for other tuberculous

lesions was made throughout the body. Absolutely none were found except in the mesenteric glands which were caseous. It is most probable that, as the result of the traumatism, the peritoneum was inflected from these glands.

Excretion of Glucuronic Acid.—M. Bial and F. O. Huber do not agree with P. Mayer in his contention that an increased excretion of glucuronic acid in the urine signifies a reduction in the oxidizing power of the body. Mayer's methods of demonstrating the presence of this acid in the urine are not reliable, since by them other acids which cannot be excluded may be thrown down. Erroneous conclusions are thus reached. It is certain that at the present time there is no method by which the presence and amount of this acid in the urine can be shown, and until such is provided the clinical importance of the various tests now in use is nil.

Munchener medicinische Wochenschrift, May 5, 1903.

Etiology of Carcinoma of the Œsophagus.—Paul Wolf thinks that chronic irritations play an important part in the etiology of carcinoma, and reports two cases of carcinoma of the œsophagus which were preceded by spondylitis deformans, and which, when taken in conjunction with other reported cases, show that the chronic irritation of the œsophagus produced by the latter condition is at least a predisposing factor in the causation of carcinoma of the same. Both of the patients were over fifty years of age and had suffered from both complaints for some years. The diagnoses were confirmed at autopsy, and from the character of the lesions present there can be no doubt but that the spondylitis antedated the carcinoma. Moreover, that such was the case could not be doubted from a consideration of the clinical histories.

Anthrasol in Dermatology.—A. Sack and H. Vieth recommend the local use of this new preparation in the various skin diseases, especially the parasitic, and in pruritus from various causes. When pure anthrasol is in the form of an oil. It may, however, be diluted to any desired degree with alcohol, aceton, fatty oils, paraffin, vaselin, lanolin, oxide of zinc, etc. The most marked immediate results of its application are the lessening of irritation and itching. The authors have used it in about eighty-five cases, in all of which it gave the most satisfactory results.

French Journals.

Intestinal Lavage in the Treatment of Muco-membranous Colitis.—Maurice De Langenhagen concludes that, whatever inconveniences may be attributed to intestinal lavage (dilatation of the intestines, irritation of the mucosa), they are without foundation. Other criticisms (nervous intolerance of certain patients, spasms and intestinal contraction, maintenance of intestinal atony), have only a very slight foundation and in a small number of subjects. The total number of cases in which lavage has not succeeded has certainly not been more than twenty in one hundred. Consequently, the physician ought always to try in the first place a therapeutic proceeding, which counts on active success in the proportion of four-fifths; if later it is found that this proceeding is not successful, it can be stopped, but it will not be followed by any disorder or any complication really harmful to the patient. It ought to be used, not only for the purpose of evacuating the intestinal contents, but also to cleanse the walls of the intestines and to act as a veritable dressing to the mucosa.—*La Presse Médicale*, May 13, 1903.

Typhoid Fever, Premature Labor, Diagnosis of Cholecystitis, and Operation Seven Days after Labor; Recovery.—Doléris observed this patient. She was delivered of a living child before term. Before delivery she was running a temperature. After delivery abdominal pain developed, and later constant diarrhœa. The spleen enlarged. Rose spots appeared. The diagnosis of typhoid fever was confirmed. Sero-diagnosis was positive. Bilious vomiting began and a painful tumor was felt in the region of the gall-bladder. Cholecystitis during the course of typhoid fever was diagnosed. Laparotomy was performed. The gall-bladder was opened and found to contain purulent bile. Fixation of the gall-bladder was done and drainage instituted. The next day the patient began to improve. Examination of the liquid taken from the gall-bladder showed Eberth's bacillus. The patient recovered —*Annales de Gynécologie et d'Obstetrique*, April, 1903.

Dermoid Cyst in the Wall of a Serous Cyst of the Ovary.—Flandrin describes this case. The patient was a woman of thirty-six years, mother of a child of seven years, and pregnant five months. There was a very large cyst of the right ovary, having the right hypertrophied tube like a long pedicle. The tumor filled up the entire abdominal cavity, and covered over the uterus. It was polycystic, with three or four pockets containing several liters of liquid and a multitude of small cysts. One part was particularly hard and was made up of a group of small cystic cavities over-distended with liquid. On section of this part several large drops of oily liquid came out, with débris of a sebaceous material, in the midst of which were many hairs. On the internal surface of the dermoid cyst was a piece of skin, on which was a tuft of hair. Ovarian cysts should always be carefully examined.—*Gazette de Gynécologie*, March 15, 1903.

A Uterine Fibroma and Cystic Kidneys.—J. A. Doléris and P. Algret declare that in cases of clear urinary affections, the question of intervention presents itself as a problem very delicate to solve. If, in fact, operative success has freed certain patients from serious uræmic troubles, occasioned by the presence of the fibrous tumor, a certain number of cases of death are undoubtedly due to renal lesions, apparently benign. Prolonged chloroform anæsthesia gives to renal lesions a sudden gravity because it constitutes an artificial intoxication added to a functional intoxication, that has been compensated up to this time. The ideal proceeding would be to substitute for this toxic anæsthesia an anæsthesia which has no harmful effect upon the kidneys. In renal troubles caused by fibroma which has to be removed, is it not preferable to have recourse to lumbar anæsthesia by cocaine rather than to chloroform? Is ether in a parallel case not less dangerous?—*La Gynécologie*, April, 1903.

Appendicitis and Opium.—Charles Krafft states that he has endeavored to prove two points: (1) That surgeons do not employ opium as treatment for periappendicitis, but simply to quiet the pain and peristalsis attendant upon the operation; (2) That purgatives and lavage are dangerous, because the peritoneum, always inflamed in periappendicitis, can only be disturbed in its work of encapsulation, if it is stirred up by irrigations, either by mouth or rectum. Operation is the only rational treatment in appendicitis, and opium is an adjuvant. By the intestinal repose that it secures it favors the formation of adhesions. Lavage and purgatives can be dangerous; they are always useless and ought to be proscribed as soon as the surgeon determines sensitiveness localized at McBurney's point.—*Revue de Chirurgie*, April 10, 1903.

Spinal Lymphocytosis and Ocular Affections.—De Lapersonne reports seventeen observations of lumbar puncture with examination of the cerebrospinal fluid according to the technique recommended by Widal, Sicard, and Ravaut. More than three or four cubic centimeters of liquid should never be withdrawn, and the patient should be made to lie with his head low for several hours. In the case of neuritis, choroiditis and recent syphilitic iritis lymphocytosis has always been found. There have never been any grave results after these punctures. This method allows a certain diagnosis of syphilis, the opportunity of mercuric treatment, and the establishment of a prognosis of the affection. When the lesion is retrogressive and old there is no lymphocytosis.—*Le Bulletin Médical*, May 13, 1903.

Indications and Contraindications for Sea-baths.—A Robin and M. Binet report some interesting work on this subject. Sea-baths are indicated in anæmics and chlorotics, in whom metabolism, especially oxidation, is diminished. But they are contraindicated in the anæmics in whom the elementary chemical activity is increased anæmias by excess). They are indicated in the obese in whom metabolism is decreased, but contraindicated in those whose metabolism is above par. They are indicated in those predisposed to gout, in chronic autointoxications of gastrointestinal origin, in phosphaturic neurasthenics, and in nervous troubles consecutive to febrile maladies, and in certain diabetics in whom nutrition flags.—*Le Bulletin Médical*, April 25, 1903.

Tetanus after Injections of Gelatinized Serum.—Dieulafoy reports the case of a tuberculous patient who had received an injection of gelatinized serum to arrest hæmoptysis. The gelatinized preparation had been made with all the desirable aseptic precautions. Tetanus developed eleven days later; death occurred in twenty-two hours. At autopsy a very small sub-aponeurotic abscess was discovered, at the point of infection. The tetanus bacil is was cultivated and was found in the pus in pure culture. There have been twenty-three cases of tetanus recorded with details similar to the one just reported.—*Journal des Praticiens*, May 16, 1903.

The Structural Changes Which Occur in Experimental Lead Poisoning.—G. Fasoli finds that grave histological changes occur and are the following: (1) Circulatory changes, shown by stasis, which is sometimes marked, followed by cyanotic atrophy in the spleen, and intestinal hemorrhages. (2) Profound cellular changes, as cloudy swelling and fatty degeneration of the cellular protoplasm, especially of the kidneys and liver. (3) Changes in the red blood cells, clearly shown by the enormous amount of blood pigment found in the spleen of the animal experimented upon.—*La Riforma Medica*, May 6, 1903.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

SECOND DAY—WEDNESDAY, MAY 13—MORNING SESSION.

Acute Lymphatic Leukæmia.—Dr. A. O. J. KELLY of Philadelphia read this paper, reporting four cases of this disease, as follows: The first case showed seventeen to thirty thousand white blood-corpuscles. Abscess of some variety was suspected, but later a differential count of the white blood cells showed the lymphocytes in a proportion of 93 per cent.; the second case was that of a young woman who had been delivered of a child a short time before, in whom the leucocytes ranged between 200,000 and 400,000, the lymphocytes were later found to be in a proportion of 98 per cent., previous to which the case had been considered one of postpartum sepsis; the third was in a young boy in whom sepsis was suspected, but later the differential count of the white cells showed a percentage of lymphocytes to the amount of 98 per cent. The fourth case was that of a man forty-eight years old, with an enlarged spleen and an evident gumma of the liver; the leucocytes varied in this case between twelve and thirty-eight thousand. In cases two, three, and four the conditions much resembled that of infantile scurvy. Lymph glands, sinuses, and nodes as such, could not be recognized. There were no myelocytes or granular cells in the bone marrow. The author looked upon the granular cells of the bone marrow as the common ancestor of both lymphocytes and myelocytes; the bone marrow was the portion of the body at fault in this disease. Myelogenous leukæmia is not to be regarded exclusively as a disease of the bone marrow, but other lymphoid tissues, may produce the lymphocytes in the blood. The lymphatic type might occur without enlargement of the glands. Many cases of the lymphatic variety have been called, in the past, before the time of blood study, typhoid fever, and *vice versa*.

Report of an Autopsy and the Microscopic Findings in a Case of Acute Leukæmia.—Dr. F. P. KINNICUTT of New York City read this paper, reporting a case of general progressive debility with anæmia, hemorrhages, and engorgements of the lymphatic tissue. The spleen was both enlarged and tender, as was the liver. Previous to the death, which had occurred six days after the doctor had first seen the case, there had been bleeding from the gums and mucous membrane. The daily output of urea and uric acid was in a ratio of 1 to 40. The thymus gland was found enlarged at autopsy. The white masses of substance which were first seen in the lungs on autopsy proved to be lymphoid tissue. The connective tissue of the liver was increased, but the epithelium was little altered. The endothelium was swollen. The spleen showed general infiltration; nucleated red blood-corpuscles were either scanty or absent. The intestinal wall was altered only at Peyer's patches, due to an increase of the lymphoid cells in that region. No myelocytes were found in the bone marrow. Toward the end there was a rapid diminution in the white blood cells unless there were present an intercurrent or a secondary infection. The myelocytes showed a progressive increase from the very beginning.

A Clinical and Pathological Study of Two Cases of Splenic Leukæmia, Presenting Early and Late Stages of Cirrhosis (Early and Late Stages of Banti's Disease).—Drs. GEO. DOCK and A. S. WARTHIN of Ann Arbor read this paper paper, presenting the clinical and pathologic findings in these cases.

Dr. DOCK showed two cases of splenic leukæmia, one of which had been operated upon for removal of an enormous spleen, but the patient had succumbed five days later. The second case had an enlarged spleen with ascites for the last six years. Abdominal section was done and cirrhosis of the liver was found. In both cases the hæmoglobin ranged between 60 and 70 per cent., the red blood-corpuscles about 3,500,000; the whites were increased.

Dr. WARTHIN said that both cases presented typical pictures of splenic anæmia; there was stenosis of the portal vein with calcification of the vein wall. The most interesting feature of the two cases was an extensive new formation of lymphoid tissue throughout the root of the mesentery and in the prevertebral adipose tissue. In one case (early stage of cirrhosis) the new lymphoid tissue resembled splenic pulp in structure, the larger nodes having the character of accessory spleens. In the second case (advanced cirrhosis) the lymphoid tissue presented the charasteristics of hyperplastic hæmolymph nodes. All these showed in their blood sinuses the presence of great numbers of phagocytes containing disintegrating red cells and blood pigments, the degree of hæmolysis apparently being much greater than that occurring in pernicious anæmia. There were no evidences of red blood cells destruction in the spleen. On the other hand, the bone marrow showed great numbers of red-cells and pigment phagocytes, as in the hæmolymph nodes. Similar changes were found in the hæmolymph-nodes of the case, showing early stage of cirrhosis, but were much less marked; in this case some evidences of hæmolysis in the spleen were also found. The splenic function of hæmolysis was entirely lost in the early stage, and was compensated for by the hæmolymph nodes and bone marrow. It was, therefore, probable that this hæmolysis was only compensatory for the lost splenic function and not the direct result of an intoxication, as in pernicious anæmia. In splenic anæmia one might, therefore, speak of a compensatory hæmolysis in pernicious anæmia of a toxic condition.

Dr. CABOT of Boston said that he had never seen the two types of leukæmia mixed, and that there was no evidence to establish the fact that this condition of mixed types was possible. He was unable to make up his mind to the belief that lymphatic leukæmia was an entity. One might get cases in which the condition of acute lymphatic leukæmia was simulated by other diseases; he had known it to exist in whooping-cough, and in one case of a young surgeon who had become infected at the operating table; in this case all the glands of the body had become swollen, and the examination of the blood revealed a condition identical with that of a characteristic leukæmia. However, all of these cases had recovered by two weeks, and there remained in the blood no evidence of the previous seeming pathologic condition.

Dr. W. H. WELCH of Baltimore said that Dr. Dorothy Reed's study of this condition showed that lymphocytes polymorphonuclearneutrophies were derived from a common ancestor. That Dr. Caspar Gilchrist's experiments with urticaria, in which an active migration of the lymphocytes to the wheals had been made out, showed most conclusively to his mind that this cell had the faculty of a amœboid movement. He reported a case of calcification of the portal vein in which death had been preceded by the vomiting of large quantities of blood.

Dr. WM. OSLER of Baltimore said that there should be recognized two types of lymphatic leukæmia, acute and chronic. The chronic cases might go on for years, and he was sure that the physicians of New York City would remember the very celebrated case in which a patient, in their city, had gone on for years with a leucocyte count of over 200,000, most of which were true lymphocytes. Acute lymphatic leukæmia very often resembled ordinary sepsis.

Dr. DOCK said, in conclusion, that he had had a case of mixed-celled lymphatic leukæmia, and believed that it really could exist as such a condition.

The Relation of Chronic Enlargement of the Spleen to Anæmia in Infancy.—Dr. JOHN L. MORSE of Boston read this paper, saying that enlargement of the spleen occurred very frequently in children. All pathological changes in the blood of children were just the same only more exag-

gerated than in adults. Lymphatic leukæmia in children showed the superficial lymph glands, the liver, and the spleen enlarged. There was a diminution of the red blood cells and of the hæmoglobin, polychromatophilia, poikilocytosis, and an increase in the polynuclears. The engorgement of the lymph nodes, liver and spleen were independent of each other. In discussing the question of the etiology in his cases, he found that rickets was present in two cases, but did not consider it of any importance. Syphilis was also present in two cases, but except for the effect upon the digestion he considered it of no value as a factor in the production of the disease. To his mind the prime factor was digestive disturbance, which was present in almost all of the cases. When anæmia, lymphatic, splenic, and hepatic enlargement were present in a case it was due to no cause other than digestive disturbance. The nucleated red blood cells were not important factors in the prognosis in children, as was the case in adults. The enlargement of the spleen usually disappeared after a comparatively short while. There was no relation between the size of the spleen and the final outcome of the condition.

Dr. Osler remarked that enlargement of the spleen in children was common under two years and might mean nothing, but this did not hold good in later periods of life.

Chronic Cyanosis and Enlarged Spleen, with Polycythæmia: A New Clinical Entity.—Dr. William Osler of Baltimore read this paper, reporting three cases in which the above cited symptoms had appeared in patients without other pathologic, organic changes. The first case was that of a physician fifty-four years old who had been permanently cyanosed for a long time; there was no shortness of breath or discomfort on breathing, but the pulse was rapid. Examination of the chest showed that there was present neither emphysema nor cardiac lesion. The blood count for the reds varied between eight and ten millions. There was a slight enlargement of the spleen. Examination of the renal excretions showed the presence of an occasional tube cast, hyaline in character. The blood-pressure was increased, being equivalent to 225 milimeters of mercury. The second case was that of a male, very much cyanosed, and constipation was extreme. There was also present enlargement with pain of the spleen. The blood count for the reds showed a variation between seven and eleven millions; there was no increase in the white blood cells. Although the cyanosis was extreme, there was neither disease of the heart nor the kidney; the hæmoglobin in the blood was increased, and the specific gravity was higher than normal. The third case was that of a woman forty-nine years of age who had presented chronic cyanoses, but no emphysema or heart disease. The red blood cells varied between nine and eleven millions to the cubic centimeter. On reviewing the literature the author had been able to find but five cases which simulated those which he had just reported; those reported cases by other authors had not been recognized as a separate clinical entity. Chronic cyanoses was present in emphysema, congenital heart disease and the cases under discussion, and those were the only ones which were ever able to walk into the physician's office. It was possible to get extreme cyanoses without polycythæmia. One might see cases of extreme hyperæmia with extreme anæmia. Polycythæmia as a clinical condition was common, being seen in cholera, gastrorrhœa, and many other conditions. However true polycythæmia was met with in cases of change of altitude, congenital heart trouble, and in that group represented by the author's cases.

Dr Cabot of Boston had seen four such cases as were pointed out by Dr. Osler. However, in two of them an important point to his mind had been an enlargement of the liver. There was a brownish hue given to the skin, in all probabillity, by the presence of a chronic congestion. Venesection gave marked relief for a short while in one of his cases.

Dr. F. C. Shattuck of Boston referred to three cases of a similar kind which had occurred in his practice. One case was so marked as to cyanoses that for a long time in the morning he had been accustomed, to expectorate large quantities of blood. On one occasion his family physician told him that the patient had vomited at least one gallon of blood and did not seem to be in the least bit disturbed by the loss of such a large quantity.

Dr. Osler, in concluding, said that his first case had protrusion of the eyeballs, which had been noticed in several of the cases mentioned by the gentlemen discussing his paper. Headache, which had been so common in the majority of his cases, was very satisfactorily relieved by the administration of generous doses of sodium nitrate.

AMERICAN SURGICAL ASSOCIATION.

SECOND DAY.

The Therapeutic Value of the X-Ray in Sarcoma.—Dr. Wm. B. Coley of New York read this paper. He said that a year ago he had presented to the members ten cases of sarcomatous growth in which he had made use of the *x*-ray, and he now wished to add twenty-six more to the series. Two-thirds of the cases had been of the round-cell variety. His results with the employment of the *x*-ray alone had not been at all encouraging, only four cases having been temporarily relieved. His continued observations led him to the conclusion that the rays in themselves were of little value, but as an adjuvant to the mixed toxins they possessed a distinct therapeutic use. He cited several cases in which the rays had caused the entire disappearance of the sarcomatous growth, but in every case there had been a distinct and fatal recurrence. The dangers arising from the employment of the combined agents were not great if sufficient care be employed in their exhibition. They consisted chiefly in the establishment of more or less profound toxæmia from absorption of the broken-down neoplasm. A remoter danger consisted in the possible formation of metastases from this cause. In conclusion, he said that the rav unquestionably inhibited the growth of sarcomatous tumors, but that it had no apparent effect on preventing their recurrence, and that in any case the treatment, if at all successful, must be employed for months or even for years.

Some Contributions to the Surgery of the Gastrointestinal Tract.—Prof. Joh. v. Mikulicz-Radecki of Breslau, Germany, presented this paper. After the ovation which greeted his appearance had subsided, he said that he was sorry to have brought to so distinguished a body such a very small contribution, but he wished to speak of three procedures which had recently proved of great interest and value to him. The first was of the recognition and treatment of the condition which he had named cardiospasm. The second bore upon gastric ulcer and the third upon intestinal intussusception. He said that while the condition of cardiospasm had only begun to be recognized, and that therefore but fifteen cases had been recorded, five having occurred in his own practice, nevertheless there was ground to believe that it was a pathological entity of considerable frequency. The symptoms occasioned by the spasm of the muscles at the cardiac end of the stomach or lower œsophagus were so vague and indeterminate as to render a diagnosis based upon purely subjective signs impossible. He therefore had devised an œsophagoscope, which portrayed very readily the pathognomonic objective signs with precision and clearness. He had formerly operated upon these cases by making an incision into the stomach of sufficient size to introduce the whole hand, in order that he might guide a dilating instrument into the almost closed cardiac end of the stomach and thence into the œsophagus, but a further experience with these cases had led him to conclude that a very small gastrotomy was all sufficient, and indeed he was of the opinion that with the perfecting of his œsophagoscope he would be able to do all the work from above. Simple dilatation to the extent of seven centimeters sufficed to afford absolute

relief of all symptoms. Both as an aid to diagnosis and to prove that the intervention undertaken had been successful, the *x*-rays were of paramount value. Bearing on gastric ulcer, he said that there was yet much to know about this much-talked-of condition, he wished to call attention to the ulcerations of the bowel in the upper region of the jejunum, with special reference to their etiology. From an observation of numerous cases, he had been forced to the conclusion that those patients upon whom anterior gastroenterostomy had been done were essentially the ones in whom we might look for the possible occurrence of this rare but very fatal form of ulceration. This he explained on the ground that in doing the anterior operation a portion of the jejunum relatively low down was taken. This technique of necessity made use of a section of the gut, which was further removed from the stomach in the case of the posterior operation, and hence the gastric juice, when turned upon its delicate membrane, was apt to cause necrosis and ulceration. He considered this a very important reason for the avoidance of anterior gastroenterostomy. It was a factor in determining him in his preference of Finney's operation of pyloroplasty over the usual method of gastroenterostomy.

Intestinal intussusception might, he said, give rise to the formation of tumors so large as to demand the utmost surgical skill for their successful removal. He cited two cases in which the condition had been so extreme as to necessitate the creation of a new technique directed toward their relief. It consisted in a longitudinal splitting of the intussuscipiens with a ligating of the part to the abdominal wall and a subsequent removal of the intussusceptum from above, the tumor being so big as to render its delivery through the rectum impossible. His results had been so gratifying that he felt justified in presenting his technique.

A Personal Record of the Surgery of the Stomach.—Dr. B. S. A. Moynihan of Leeds, England, presented this paper. He said that although the non-malignant diseases of the stomach had been much debated, and despite the fact that the English surgeons in particular had given their best energies to the exploitations of this subject, there yet remained much that was hidden from us. In recognizing, however, that the great bulk of *all* lesions were due to ulcerations, an immense step forward had been taken. The symptoms of hemorrhage from the stomach, he said, were naturally as varied as the conditions which gave it birth. From an acute ulcer the hemorrhage was sudden, copious, followed by profound though transient anæmia. The pulse was frightfully depressed and the bleeding was characterized by a tendency not to recur. From chronic ulcer, on the other hand, might be expected a variety of hemorrhages, which can be grouped as follows: First, those which were latent but continuous, and which could only be recognized by the most careful laboratory analysis; second, those in which the hemorrhage was of an intermittent, copious type, although transient and usually self-limiting. These patients usually presented as their most prominent symptom an intractable indigestion and anæmia. In the third class of cases the hemorrhage was rapidly repeated. It occurred, unlike the previous type, only after repeated classic warning, and was abundant and unceasing. It might amount to a pint, and characteristically recurred at short intervals. The fourth type was happily a very rare one, consisting of those cases in which the ulcerative processes had involved some great trunk, such as the aorta or the splenic artery. The treatment of hemorrhage from the acute form should almost always be of a medical type, because very few of these failed to yield to this form of therapy. In the second and third type gastroenterostomy seemed to him to be distinctly the operation of choice. He called attention to those baffling cases of pronounced hemorrhage in which the mucous membrane of the stomach seemed literally to weep blood from every pore. There was no means at the surgeon's disposal save gastroenterostomy for the relief of such a condition. The treatment of hemorrhage from chronic ulcer depended largely upon the pathology of the condition. It could readily be observed in any one of these cases, even upon the operation table, that the arteries almost always remained open, being held in this position by the dense mass of sclerotic tissue in the base of the old ulcer. Hemorrhage from them was controlled, not by a shutting of their coats, but by thrombus formation. This explained very readily the recurrence of hemorrhage, and seemed to the author to be one of the most salient reasons for performing gastroenterostomy. He felt certain that this was the most positive means of preventing gastric motion or dilatation of the organ. One or other of these factors being always responsible for the tearing off of the clots. So certain had he become of the justice of his conclusions that gastroenterostomy rapidly performed was all sufficient for the cure of all curable types of hemorrhage that he had long since given up all and any attempts to find the ulcer or the bleeding point. The symptoms of chronic ulcer, he said, were simply those of gastralgia. The presence of hemorrhage was by no means necessary to justify the diagnosis of chronic ulceration. He recognized that it was difficult always to differentiate between the inflammatory mass so characteristically caused by this condition, and malignant neoplasms, but he believed that by the naked eye and by the touch they could, as a rule, be identified. The malignant growth had a nodular look and touch, and was usually spread over by a dirty-looking gray exudate, whereas the inflammatory growth was clean, of normal color and smooth. He said that pathological conditions due to ulceration were innumerable; that the time had practically come when all dyspeptic troubles had been taken out of the hands of the internist, because they had been shown to be due to physical rather than to chemical causes. Bands of adhesions could readily so warp the stomach as absolutely to interfere with its digestive function. Of hour-glass contractions, he said that the two loculi might be equal in size, but because of the physical conditions imposed upon each being so utterly different, there was small probability that they would long so remain. He refuted the idea that most hour-glass deformities were congenital in origin, and believed that they had in England adequate proof for the assertion that almost all were acquired. The symptomatology of the condition had been very thoroughly worked out, and so concise were the methods to-day, as to enable any careful observer to make a positive diagnosis. He believed that the more complicated methods of transillumination and of the introduction of rubber bags into the stomach were absolutely unnecessary, because, by the careful use of water and of carbon dioxide, all necessary data could be obtained. On the other hand, however, he said that the treatment of the condition might be extremely difficult because of the density of the adhesions. Another important factor not to be overlooked was the possibility of joining the pyloric sac rather than the cardiac loculus to the gut. This, of course, would fail to relieve the conditions, and called for a double operation of one of the following types: gastroplasty, double gastroenterostomy, gastrogastrostomy, or partial gastrectomy.

Dr. W. W. Keen of Philadelphia, in opening the discussion, said that Professor von Mikulicz had dealt with subjects almost entirely unknown to him. He had had the privilege, however, while in Breslau, of seeing the Doctor use his œsophagoscope, and had been so much impressed with its work as to have begun its employment immediately on his return. As to peptic ulcer of the jejunum following anterior gastroenterostomy, he had yet to see a case. He gathered that the method described for the removal of the intussusceptum closely resembled Maunsell's method of enterorrhaphy. He believed that the time had come when the radical surgery of the stomach presented far less danger than the waiting policy in any case of ulceration, and cited two graphic histories in support of this view.

Dr. W. J. Mayo of Rochester had had but one case of cardiospasm, in which he had performed gastro-gastros-

tomy to put the part at rest and had been gratified by obtaining a cure after eight months. He took exception to Mr. Moynihan's liberal and broad endorsement of the employment of gastroenterostomy for the cure of chronic ulcer, basing his criticism upon over a hundred cases which he had had under observation. That all such cases improved immediately after the operation and that the hemorrhage was invariably controlled he did not deny, but he felt convinced that the efficacy of the treatment attended upon the continued patency of the fistula. His observations led him to believe that this lumen diminished directly in proportion to the increase of size of the pylorus. In almost all these cases the pyloric opening was very much occluded by the presence of congestion due to the irritation of the ulcer, and naturally when that was put at rest and the irritation allayed, the pylorus began to open. At this very moment the fistula began to shrink, and so soon as it had closed sufficiently to force the food over the ulcer-bearing surface, the symptoms repeated themselves and secondary operations became imperative. He therefore believed that the operation of the future would consist in the excision of the entire ulcer-bearing region, thus removing all possibility of complications or sequelæ.

Prof. Hermann Tillmanns of Leipzig, Germany, said that he was not prepared to discuss the paper, but desired to take this opportunity of publicly thanking the American medical profession for the courtesy he had received at their hands. He said that he worked best who helped humanity; that science and art were international, and that the physicians and surgeons of America and Germany were as brothers in conducting their uplifting work. Germany, he said, had a great feeling of sympathy for America because of the predominance here of Teutonic blood, and he hoped that the association would prosper in all its undertakings.

Dr. Rodman of Philadelphia said that Mr. Moynihan had made an eloquent appeal for gastroenterostomy as a relief for chronic ulcer, but he himself believed that, while no doubt it should be performed for the treatment of acute and chronic hemorrhage of the stomach, it had its very distinct limitations. One of them no doubt consisted in the suggestion of von Mikulicz that under certain conditions it might lead to jejunal ulceration. He urged the early performance of pylorectomy or partial gastrectomy with a removal of the ulcer-bearing surface rather than a recourse to the more dangerous medical method.

Dr. L. Freeman of Colorado mentioned a case in which he had performed gastroenterostomy for acute hemorrhage occurring in a hitherto healthy man. There was immediate primary recovery but subsequent death from hemorrhage.

Dr. J. M. T. Finney of Baltimore said that he desired to emphasize two points: First, that from Dr. Moynihan's classic paper, it could be seen that for the prevention of hemorrhage from gastric ulcer, rest and drainage were absolutely indicated. He believed that by pylorectomy so performed as to give a maximum opening at the most dependent spot, these indications could be much better met than by any method of gastroenterostomy.

Dr. L. M. Tiffany of Baltimore said that whereas dyspepsia had until recently been considered purely a medical disease, progress in the surgery of the stomach had unquestionably demonstrated that almost all intractable cases would yield to proper surgical intervention.

Dr. N. B. Carson of St. Louis took exception to Dr. Mayo's statement that gastroenterostomy fistula would close so soon as the lumen of the pylorus became patent.

Dr. B. F. Curtis of New York spoke of a case of cardiospasm in a child nine years of age which he had successfully treated by gastrotomy and dilatation. He believed that occasionally cases of hemorrhage from gastric ulcer might be satisfactorily treated by the ligation of the artery in close proximity to the lesion. He doubted that any one could differentiate between malignant and non-malignant conditions without the help of the microscope.

Dr. Moynihan, in closing, said that the geography of gastric ulceration yet remained to be worked out. It at present seemed to him that whereas in England hemorrhage and perforation were relatively common, here the more frequent complication of ulceration was malignant implantation. The treatment of gastric hemorrhage arising from chronic ulceration resolved itself into the prevention of this condition. He found himself unable to agree with Dr. Mayo that the fistula would close as the pylorus opened, and believed that probably the difference in the results obtained here and in England depended upon the employment of different techniques. While he was at present wedded to gastroenterostomy, he had been very profoundly impressed by the observations of Dr. Rodman and of Dr. Mayo and others that the operation of the future would consist in an extirpation of the ulcer-bearing area of the stomach.

Prof. von Mikulicz, in closing, said that he frequently performed a jejunostomy for the purpose of treating the patients during the first two weeks even after posterior gastroenterostomy, and always if the anterior operation were done.

The Therapeutic Value of the X-Ray.—Dr. Arthur D. Bevan of Chicago read this paper. He said that he had nothing strikingly new to present, but desired to offer something in the line of conclusions which he and his colleagues thought were pretty definite and based upon sound evidence. In the first place, there was no possible doubt that the rays did destroy superficial carcinomatous cells, as could be frequently evidenced in epitheliomata. They had come to the conclusion that the distance beneath the surface at which it was safe to say that the rays were really effectual should be one cm. If absolutely superficial or within this distance of the surface, the cells could be counted upon to disappear after twenty exposures with a soft tube at a hundred volts and two amperes. One exception to this was the lip, in which the outlook had been shown not to be so favorable, both as to secondary glandular involvement and from the fact that the mucous membrane of the region was peculiarly susceptible to *x*-ray dermatitis. Probably one of the best examples of carcinomata which had been subjected hundreds of times to the *x*-rays were those of the breast, and there was abundant evidence to show that these were at least not helped at all; it was a matter of some doubt whether or not the treatment had in some cases increased the rapidity of general carcinomatosis. Aside from the question of superficiality of the growth, the rays were effectual to a greater or less degree, depending upon the actual vitality or resisting power of the cells themselves, upon the rapidity of their growth and upon the rise of the neoplasm, their value being in general inversely as its size. Bearing on the question which has recently been asked, with a good deal of pertinence, whether, under certain unknown conditions, the rays did not directly stimulate malignant growth, not only in a metastatic manner but actually at the sight of exposure, he agreed that this still remained a moot question. To him the most interesting problem in connection with the whole matter, aside, perhaps, from the last-mentioned, was the possibility of being able to extend the power of the rays from the surface to greater depths, so that instead of being able to get results at the depth of one c.m. only, as now, we might be able to destroy the breast and other deeper tumors. This, he thought, might be accomplished perhaps along two lines, viz., the physicists might improve the power of the rays without augmenting their malign characteristics or, possibly, by the introduction of some chemical into the parts prior to their exposure to the ray, the vitality of the cells might be so reduced as to enable us to kill them with the rays as at present used. It was well known that the rays, if turned upon certain solutions of iodine, either metallic or appearing under the form of one of its salts, as potassium or sodium iodide, produced decomposition of the iodine and a liberation of the drug in what was a very active and, perhaps, a nascent form. He reported the experiments

made by himself and his colleague along these lines. They had given to their work the name of radio-chemic therapy. They had found it of distinct value in the treatment of actinomycosis. They gave the patient large doses of potassium iodide, and then, with a goodly amount of the drug circulating through the tumor, they turned upon it, to the full tolerance of the patient, an *x*-ray.

The Value of the X-Ray in Superficial Epitheliomata and Tuberculosis.—Drs. W. L. Rodman and G. E. Pfahler of Philadelphia read this paper. Dr. Rodman said that his colleague had done the bulk of the work. In studying 234 cases of epitheliomata, they had found 63 per cent. to have been cured and 36 per cent. much improved by the *x*-ray. To accomplish this the average number of treatments had been twenty-five and the time occupied a little over eight weeks. In rodent ulcer 43 per cent. had showed marked improvement. The treatment in this type of tumor required more patience than in the foregoing. Of lupus vulgaris they had been able to collect seventy-five cases treated by the ray, sixty-five of which were reported cured. Here, again, the time had been eight weeks, but the treatments had been more frequent, viz., forty. Lupus erythematosus, curiously enough, was shown to be just as difficult to cure. In general, the final results compared most favorably with other methods of treatment. In tuberculous glands the rays had been used in ten cases, with favorable results in all, but it was in Hodgkin's disease that the most startling revelations were produced by this form of treatment, a number of cases having been recorded in which glands very deeply placed had speedily disappeared. So far as the action of the rays was concerned, very little was as yet known about it, but certain it was that in addition to the blood vessels closing, elastic tissues developed in the surface at a rapid rate. He said the question of personal idiosyncrasy to the rays was not a matter to be passed over lightly, because dermatitis and loss of hair had taken place in one patient who was exposed a single time to a tube under exactly the same conditions as another patient who had been treated for two years and a half with great regularity. He concluded that, for the treatment of slow growing and not highly malignant tumors of the face, the rays were indicated because of their efficacy and excellent cosmetic effect. In lupus it was practically a certain cure. Under all other conditions, however, the rays were simply an adjuvant to older methods of treatment.

Some Experiences in the Treatment of Inoperable Malignant Disease by Means of the X-Ray.—Dr. Alexander B. Johnson of New York reported ten cases which he had had under treatment in the last two or three years. Of these he said that eight were already dead, one was in a not altogether promising condition and one was, to all appearances, cured. He said that while this report was in itself somewhat gloomy, yet it must be remembered that the single case cured was, like the others, absolutely beyond the reach of any other treatment. For inoperable cases, then, and for these alone, he would consider the use of the *x*-rays justifiable.

Dr. F. H. Williams of Boston, in opening the discussion, said that he had always studiously avoided attempting to treat any case with the *x*-ray in which there was glandular involvement. The small superficial growths, which, as a rule, yielded so easily to intelligent *x*-ray therapy, might be considered as absolutely curable with the *x*-ray, since he had a number of patients who had passed the three-year limit. So far as those cases in which the ray had been used when surgery had failed, he believed that it was conservative to say that they had occasionally stopped the malignant process. That harm might occasionally be done by the ray was now doubted by no one, but it might be freed of its danger by the use of the fluorometer, an instrument which he had devised for measuring the amount or rays which the tube was giving out. He had noted that the disappearance of the glands in Hodgkin's disease was ephemeral, showing thus the action to be purely local and symptomatic.

Dr. W. J. Hearn of Philadelphia said that he had no patience with the use of the *x*-ray except in the treatment of rodent ulcer and of cheloid, because with our modern aseptic methods we were able to remove these growths almost without a scar.

Dr. Bevan, in closing, said that there were two dangers to which he wished to call attention. Burning had occurred twice in thirty-five cases. These burns were bad and very difficult to heal. The second danger lay in the use of the rays for any form of malignant growth that was not positively superficial. He believed that before very long we should have hit upon some way to augment the present power of the rays.

Dr. Rodman, in closing, said that undoubtedly the rays properly applied constituted the best treatment for epitheliomata and tuberculosis about the face. He did not agree with Dr. Williams' views in regard to the usefulness of the treatment in tuberculous glands, because he and his colleagues had obtained very excellent results in undoubted examples of this condition. In reference to Dr. Coley's paper, he said that he had never seen a cure of small spindle-cell sarcoma by the toxins, but we all knew that such cures had been obtained. It would seem therefore that the combined treatment might do a great deal where either one singly would fail.

Dr. W. B. Coley, in closing, said that it seemed to him unquestioned that some of the deeper tumors could be influenced by the *x*-ray.

Dr. A. B. Johnson said that all operable tumors should be operated upon, except when growing from the face and if absolutely superficial. We did not as yet know the value nor the limitations of the ray. His cases had shown him that, as a rule, unfortunately in inoperable conditions, the improvement which was usually pronounced at first was merely symptomatic. He declared that the public should certainly not be allowed to get the idea that the treatment of cancer by the *x*-ray amounted to anything. Otherwise the next decade would see a great increase in the deaths from malignant neoplasms.

The Results of Operation for the Radical Cure of Inguinal and Femoral Hernia with Analysis of 1,000 Cases Operated Upon Between 1891 and 1902.—Dr. William B. Coley of New York presented this paper. He said that the unaltered Bassini operation had been done in all the hernias of an inguinal type with the single exception that absorbable sutures were used throughout. Of the total number, about 500 operated upon were children under fourteen years of age, and he wished to say that contrary to the generally expressed opinion that any kind of a sewing up sufficed in this class of cases, their statistics showed that if a Bassini were properly done, the percentage of recurrences was reduced almost to zero. He had observed in treating strangulated hernia, that in the indirect variety it was the tense external abdominal ring rather than the neck of the sac which afforded the constricting band.

Report of a Case of Gangrene with Fifteen Inches of Cæcum and Ileum after an Operation for Appendicitis; Relief of Artificial Anus after Repeated Operations.—Dr. N. P. Dandridge of Cincinnati reported this most interesting and intricate case in which he had finally succeeded in closing the fistula after two operations.

Dr. Ochsner of Chicago, in discussing this paper, said that in his opinion the reason for the failure to get union lay in the fact that the author had placed a Murphy button in tissue which was not perfectly healthy. It would have been better, he said, to sew the ileum into the ascending colon after amputation of the cæcum.

Dr. Fowler of Brooklyn said that, as he was responsible for the implantation method, he wished to say that if Dr. Dandridge had transplanted the ileum into the sigmoid instead of into the transverse colon, and, second, if he had practised circumclusion of the ileum just below

his button with silver wire, he would have prevented the passage of any material over the wound and avoided failure.

The Significance of Albumin and Casts in Surgical Patients.—Dr. John C. Munro of Boston presented this paper. He said that, at the Boston City Hospital, he had chosen a series of 500 cases in which there was reported, by the house officer, albumin and casts, and in which serious lesions of the kidneys were at any rate not in evidence. His conclusions were far-reaching, inasmuch as they led him to state that such patients were not unfitted for operation under ether narcosis. He believed that far more important than casts and albumin in the prognosis of operation upon this class of cases was the character of the specific gravity as showing the total solids excreted. A possible explanation lay in the fact that many of these patients were poor children and young adults in whom alcohol had effected a certain amount of injury and whose lives had been characterized by greater or lesser privation. From the fact that the albumin disappeared within ten days or two weeks from the mere effect of rest in bed, combined with suitable food, he believed this assertion to be true.

Dr. J. B. Roberts of Philadelphia, in discussing this paper, said that to him it was revolutionary, because he had been brought up with the idea, and had held to it ever since, that in this class of cases ether was contraindicated and prognosis was bad.

Dr. N. B. Carson of St. Louis said that he also had limited himself in these cases, particularly if they were septic, to the use of chloroform, and had noted a mortality of fully 50 per cent.

Dr. F. H. Gerrish of Portland said that it was important to know what methods had been used for the detection of the albumin.

Dr. M. L. Harris of Chicago believed that if an abundance of urine were examined, and after a centrifugalization hyaline casts could be found in small number, but very constantly. The same held true with albumin, and if the solids were normal, neither of these two ingredients were to be feared.

Dr. Munro, in closing, said that ether was the classic drug for anæsthesia in Boston, and that it had had no evil effect in these 500 cases.

The Treatment of Aneurysm of the External Iliac by Digital Compression, with the Report of a Case.—Dr. F. J. Shepherd of Montreal presented this paper. He apologized for offering to the section the details of a case treated by so comparatively old a method, but he believed that in the modern rush for new things and new techniques, much that was good was laid aside for an inferior article. He said that among the advantages to be cited for this form of technique was its freedom from danger and from the use of all instruments. It could not, of course, be employed except under those conditions in which a great number of relatively expert assistants were available, because it took so many hours of unremitting pressure to allow of clotting —indeed from time-honored custom, it had been looked upon as necessary to employ relays of students for the purpose. Consequently his patient who came into the hospital some time before the convening of these gentlemen, was put to bed and placed upon a rigorous Tuffnell treatment. After digital pressure had been exercised for twelve hours upon the carefully cleansed and powdered skin, all pulsation in the tumor had ceased, but, as a precautionary measure, it was kept up for twelve hours more. The pain in these cases, which occasionally became severe from the continued pressure, should always be controlled by morphine. His patient was cured, and now, eight months later, the mass which had been considerable at first, had shrunk almost to nothing.

Dr. R. H. Harte of Philadelphia, in discussing this paper, said that this almost forgotten method was unquestionably a good one if you had the students to do the work. A most important consideration was that it probably did a great deal in helping to establish collateral circulation which was of value for subsequent intervention in case it failed.

Dr. Joseph D. Bryant of New York said that it should not be forgotten that under auspicious circumstances a properly protected weight could be applied to the part which might be held from a pulley either by the patient himself or by a single assistant.

Congenital Malposition of Cæcum and Colon with Enclosure of Ileum and Cæcum in Membranous Sac.—Dr. Leonard Freeman of Denver read this paper. He cited a case which, under obscure symptoms of abdominal derangement, had been opened by him and found to be suffering from a huge strangulated left duodenal hernia with enclosure of ileum and cæcum in the sac. These herniæ were generally supposed to occur in Treit's fossa, but Moynihan did not agree with this in the fifty-eight cases which he recorded in his classic paper. In his case the cæcum was distended to the size of a child's head, and was gangrenous. The mesentery of the colon was unusually long, allowing of its free entrance into the sac. The latter was, on section, found to be filled with blood and débris. The general cavity was, however, absolutely free. This showed that there had been no connection whatsoever between the two.

Dr. J. C. Bloodgood of Baltimore said that he had had a case in which duodenal hernia had occurred after he had operated for simple inguinal hernia. The slipping of the gut into the fossa seemed to him to have been caused by very severe vomiting. The case became desperate, but was saved by abdominal section and a discovery of the seat of trouble.

Sympathectomy for Exophthalmic Goiter.—Dr. B. Farquar Curtis of New York presented this paper. It was a summary of his last eleven cases. He laid a great deal of stress upon the fact that for some reason unknown to himself his mortality of three deaths had been extremely high, and inasmuch as every one of his operation wounds had healed without infection, he could account for it only upon that ground that thyroidism had been responsible. It was to the symptomatology of this complication that his paper was chiefly directed. The pulse was invariably very high, but the temperature was even more extraordinary, presenting a typical curve of hyperpyrexia. That this temperature was in no way associated with septic infection was shown by the fact that it developed in the first twenty-four to forty-eight hours. The temperature seemed to be an excellent guide for prognosis, inasmuch as none of his cases which passed a hundred and three and a half degrees, lived. As to the etiology of thyroidism, he said that there were three theories usually advanced, the first having for its basis the belief that the nerves were entirely responsible; the second, that it was due to the absorption of thyroid material, and the third, that it was a sort of fibrin ferment condition induced by the absorption from the hæmatoma. To him the first seemed by far the most probable. How was it that Kocher had had so low a death rate? Probably because he had in his hemisection, with the exception of six, employed local anæsthesia. In fifty cases he had had four deaths, and all of these had occurred in the six upon which he had not used cocaine. So far as the question of choice of operation between hemisection and sympathectomy went, he believed that the Jennesco operation gave better results, and that fully 60 per cent. of all cases were curable by its employment.

Dr. T. W. Huntington of San Francisco said that if anything were to be done in these cases, it should be attended to in the early stages. He had had six cases of thyroidectomy and all had been successful. It was most important to operate upon them under local anæsthesia.

Dr. Willy Meyer of New York said that the third method of treatment which had recently been inaugurated should not be forgotten. It was the so-called serotherapy, by which the patients were fed with the milk of goats

from which the thyroid had been extirpated. So successful had this treatment been and yet so difficult of application in cities that a serum had been introduced, prepared from such goats, which had similar results. Carnivora died, he said, after total extirpation. Herbivora underwent cachexial degeneration. Omnivora, as would be expected, suffered directly in proportion to the amount of gland which was removed.

Dr. Bacon of New Haven said that there were in ophthalmic goiter two distinct pathological entities: First, that due to hyperthyroidization, and, second, the distinctly nervous type. Were there any criterion by which these two could be possibly separated? If so, it would be of obvious value, because hemisection would be helpful in one; sympathectomy in the other. The secretion in order to produce the first might be excessive or perverted. The criteria for simple excess were, first, the exactness of parallelism between the symptoms and those following the successive administration of thyroid extract; second, the effect on the patient of giving the thyroid; third, the presence of actual local difficulty; enlargement of vessels and gland. Perverted secretion was characterized on the other hand by irregularity of symptoms, one of the three predominating over the others.

Dr. Ochsner of Chicago said that seven or eight years ago he had had a patient die of thyroidism, after which he made up his mind that it had been induced by an excessive and rough handling of the gland at the time of operation. Since that time it had been possible for him to do five cases without the slightest complication following. He would advise slight drainage and the utmost care in the preparation of the patient.

Dr. Geo. Woolsey of New York cited a case which he had lost from employing general anæsthesia.

Dr. F. J. Shepherd of Montreal cited six cases in which he had had one death from thyroidism and three positive cures. He regarded the question of pathology as very important in determining whether or not to operate, and, secondly, whether hemisection of sympathectomy should be done.

Dr. J. C. Bloodgood of Baltimore said that pathology had so far given a very uniform picture of the gland, the colloid material disappearing and the acini being filled with an immense number of epithelial elements. A section of this gland looked not unlike that of the lactating breast. He considered that the best procedure was a hemisection followed by sympathectomy only in the presence of residual symptoms.

Prostatectomy and Galvano-caustic Prostatotomy; Their Present Status in the Radical Treatment of the Hypertrophied Prostate Gland.—Dr. Willy Meyer of New York read this paper. He said that there could never be any question that the radical method of attack was the most surgical. Unfortunately, however, there was a class of cases which could not be neglected, and it was in their interests that he had continued his investigations with the use of the cautery. The direct methods of treating this gland were to be preferred to the indirect, which were useful only in the line of possible adjuvants, to a Bottini. In fifty-nine cases of pronounced hypertrophy, in which no discrimination had been shown, he had cauterized the gland. Fifty-two cases recovered, three died of sepsis, two from other causes and two from spinal anæsthesia. Of the fifty-two, thirty-four were alive to-day. Thirteen of these, or almost 50 per cent., had entirely regained the power over their bladder; in thirteen the recovery was incomplete. Seventy-five per cent. had laid the catheter aside entirely. He concluded that both operations had their distinct and useful sphere, and no surgeon who professed to do prostatic work should be bound to one or to the other, because there were certain cases in which one was contraindicated.

Dr. Leonard Freeman of Denver said that he had performed twenty Bottini operations, and had concluded to reserve it, first for those cases in which a general anæsthetic could not be given, second in which the disease was incipient.

Gonorrhœal Septicæmia; Its Occurrence and Course; Report at the End of One Year of a Case of Diffuse Gonococcus Infection of the Entire Upper Extremity.—Dr. Chas A. Powers of Denver said that this germ had been found in almost every degree of purity of culture in tissues widely diversified. The term rheumatism for this condition was obviously a misnomer. He gave a detailed description of his case, which had recovered with some limitations of joint motion after the most vigorous surgical treatment. The fluid which he had removed from the numerous sites of incision was serus and thin with one exception, in which pus had been formed. Bacteriologic investigation showed that in the latter case a mixed infection was present. This might have some bearing on the problem of whether the gonococcus in pure culture was a pus-producing organism or not.

Myositis Ossificans Traumatica.—Dr. J. F. Binie of Kansas City read this paper. He said that there were various theories to explain this very unusual phenomenon, among which were the possibility of the muscle having torn particles of periosteum loose during the injury and having distributed them through its substance. Another consisted of Cohnheim's theory of embryonic remains. In his case the bone had developed by both the classic methods In the eighty-six cases of traumatic origin which he had been able to collect, he had noted that it was clinically impossible to separate them from exostomata, whether attached or free from the skeleton.

Methods of Instruction in Surgical Pathology; Lantern-slide Demonstration.—Dr. J. C. Bloodgood of Baltimore said that the object of a laboratory course was two-fold, a routine course and a systematic course. He exhibited a number of typewritten books which he had prepared for section teaching at the Hopkins. By a series of most admirable cross references, the students were able to correlate the pathology, the symptomatology, differential diagnosis, a treatment and sequelæ of every important case which came into the hospital. He showed a beautiful series of lantern slides taken from among the many used in actual instruction.

Dr. W. W. Keen of Philadelphia was so delighted with the demonstration that he said Dr. Bloodgood's books should be published in proper form, so that institutions less fortunately situated than the Hopkins could make use of them.

Intestinal Localization: A Study on the Cadaver for the Purpose of Determining to What Extent the Various Parts of the Small Intestine May Be Identified through Abdominal Wound.—Dr. Geo. H. Monks of Boston presented this paper. He said that his work had been done as yet largely upon the dead, although he had been delighted to find that it worked admirably in the few operation cases at which he had been able to employ it. In 180 loops in which he had applied the differential points, he had been able to minimize the error in localization to two feet. In carrying on this work, he had hit upon the thought of threading the small intestine upon a staff. When this was held up, it showed the attachment and obliquity of the mesentery very beautifully. It demonstrated the division of the abdominal cavity into two lesser spaces, the one to the right being small and isolated, the one to the left larger and connected with the pelvis. The fact should be borne in mind when irrigating the abdomen for cleansing purposes. The direction of the gut might be determined by noting the lines of tension made upon the mesentery. He exhibited a chart which showed very beautifully the differential points, not alone of the gut but of the omentum as well.

The Lesions Which Augment the Development of Tetanus and Other Infections.—Dr. Lewis A. LaGard of Washington, D. C., gave a descriptive and illustrative ac-

count of the histological anatomy of various gunshot wounds. The most important point which he considered as favoring the development of infection in the course of the bullet was the production of hemorrhages into the tissues. He showed a beautiful series of microphotographs, which demonstrated that these hemorrhages in distribution and extent, together with other minor lesions, increased in direct ratio to the speed of the bullet and its size. Suppuration was most frequently seen at the point of exit, which showed that the production of these hemorrhages was even a more formidable factor in inducing sepsis than the actual introduction in mass of the germs themselves, which naturally would congregate about the wound of entry.

The Operative Reduction of Old Dislocations of the Elbow.—Dr. E. Rixford of San Francisco read this paper. He reported a case in which he had obtained admirable results by the so-called bloody replacement, and in which the *x*-ray had been a most serviceable aid to him.

Dr. John B. Murphy of Chicago said that he believed in these cases an arthoplastic operation by which the aponeurosis of some neighboring vessel was placed between the ends of the bond was the operation of the future.

The Drowning of Patients in Fecal Vomit as a Complication of Operations During Appendicitis and Obstruction of the Bowels.—Dr. E. W. Andrews of Chicago presented this paper. He said that this condition should be recognized as an actual surgical entity. His attention was first called to it by the sudden death, an hour after operation, of a patient who was apparently doing well. The amount of fluid accumulated in the bowel of these cases was sometimes phenomenal, and he accounted for the drowning by a relaxation of the sphincters of the stomach, which allowed the fluid to pour up the œsophagus. These patients almost always died, no matter what treatment be used, and therefore, as a precaution, if any such complication be suspected, lavage should be resorted to. It never happened during consciousness, and was therefore an indication for the employment of spinal or local anæsthesia.

Dr. J. M. Finney of Baltimore reported three cases, two of which had been immediately fatal, the third dying later.

The Pathology and Treatment of Tardy Post-operative Intestinal Obstruction, with Report of Cases.—Dr. Ellsworth Eliot, Jr., of New York read this paper. He said that the cause of such obstruction might lie in a circumferential band in the wall of the gut; to its being held at an abnormal angle, or as was more frequently the case, to the imprisonment of the gut by bands which usually arose from the omentum. Prophylaxis consisted in the employment of the very greatest care in handling the viscera and in the covering of all suture lines whenever possible by omentum or Cargile membrane. Drains frequently occasioned danger and should therefore be small. He believed that it was desirable to wash out the alimentary canal as freely as possible, so as to dispose of all central sources of irritation; that the patient's posture in bed, as well as the position of the bed itself, should be frequently changed in all cases in which there was a probability of the formation of bands.

Dr. Ochsner of Chicago said that in cases of obstruction it was usually the cathartics and food given that killed the patient.

Dr. Eliot, in closing, said that obstruction was much more frequent after operations where drainage had been necessary, but that it might follow uncomplicated operations like that for the interval removal of the appendix. He urged that all non-absorbable knots and sutures outside the lumen of the gut should be avoided.

Traumatic Paralysis of the Circumflex Long Thoracic and Suprascapular Nerves.—Dr. F.E. Bunts of Cleveland read this paper. He said that two suits for malpractice had prompted him to look the matter up. Deltoid paralysis was, by far, the most common, it being probable that the injury to the nerve was effected in its termination in the muscle rather than at its point of passage around the bone.

Contribution to the Surgery of Cerebral Tumor.—Dr. Geo. Woolsey of New York read this paper. He said that only a very small percentage of cerebral tumors were suitable for operative intervention, but that this was simply because of our poor methods of localization. He emphasized the fact that the *x*-ray and percussion were serviceable guides. Local tenderness had been observed in 21 per cent. of cortical tumors, and in 6 per cent. of these there had been recorded external swelling. Palliative operations, he believed, to be justifiable in all conditions warranting operation. The technique had so much improved recently that the two-stage operations recommended by the English writers should no longer be necessary. Important in the technique were the absolute control of hemorrhage and the employment of drainage. He concluded that the prognosis in malignant tumors of the brain was almost as good as elsewhere in the body.

The Treatment of Surgical Shock by Adrenalin.—Dr. E. Martin of Philadelphia read this paper. He said that in adrenalin we possessed the most powerful cardiac and respiratory drug known. It was almost harmless, the lethal doses being probably much more than one hundred times as great as the dose ordinarily used to-day. In using it on patients who were septic, it should not be forgotten that it depresses the bactericidal power of the serum. In the laboratory he had been able to bring back to life dogs killed with ether after they had been, to all appearances, dead for fifteen minutes, and clinically he had been able by the introduction of from one to four c.c. of adrenalin directly into venous circulation, in a 1 to 10,000 solution, to rescue at least one desperate case from impending death.

A Case of Gunshot Wound of the Brain, in Which the Röntgen Rays Showed the Presence of Seven Fragments of the Bullet: Localization by Sweet's Method Made Operation Inadvisable.—Drs. W. W. Keen and W. M. Sweet of Philadelphia presented this paper. The patient, a young English lad, had been shot by a 22-caliber rifle about an inch above the right eyebrow, the direction of the bullet being upward, backward, and inward. At the primary operation, which consisted in the enlargement of the wound and its sterilization, a sliver of the bullet, representing about one-seventh the total weight of the bullet, was found to have been torn off and deflected upward by the bone. This was removed without difficulty. The young man had been seen by Mr. Treeves and Mr. Horsley of England, and upon their recommendation had come to Philadelphia for treatment. Dr. Sweet had determined not alone the actual position of the bullet but the presence and location of seven small fragments as well. The position in which he localized the major mass did not correspond with the track of the bullet along which lay the minor particles. This showed probably that the bullet had passed through the brain and had bounded from the posterior limitation of the skull to its present position. Inasmuch as the boy, who had some time ago begun to suffer from a numbness and paresis of the right leg was beginning to show marked improvement, it was determined not to operate upon him, because in all probability the effort would do him more harm than the continuance of the missile in the tissues. The lad was sent home with the injunction to his parents that the ball should be immediately removed if at any time in his life he developed obstinate headache, or if he ever had a single epileptic seizure.

Dr. Sweet exhibited his exquisite instrument, which is too well known to need description here.

At the executive meeting Dr. N. T. Dandridge of Cincinnati was elected President for the ensuing year. Place of next year's meeting, St. Louis, Mo.

FOURTEENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Madrid, April 23–30, 1903.

SECTION ON INTERNAL MEDICINE.

Curative Treatment of Pulmonary Tuberculosis.—Dr. A. Sanchez Herrero of Madrid read this paper. The varous modes of treatment of this affection at present employed, he said, had but slightly reduced the mortality. The proportion of cures by creosote, guaiacol, and their derivatives did not exceed 5 per cent.; that by balsam of Peru, cinnamic acid, and cinnamate of sodium, as employed by Landerer, was less than 20 per cent.; that by arsenical preparations, epecially the cacodylates, was entirely negligible; the various tuberculins were injurious, and Maragliano's serum was worthless in the opinion of everybody except Maragliano himself; and finally the sanatorium treatment was often ineffectual, besides being inapplicable to the majority of cases. The author had employed cinnamate of sodium in four-per-cent. solution, after Landerer's method, with the result of four deaths and one recovery; the latter he attributed to the fact that the case was a very mild one. He had, however, subsequently modified Landerer's procedure with excellent results. He used the four-per-cent. solution, but gave it by subscapular injection in doses from ten to twenty times greater than those used by Landerer. The first day he injected 3 c.c., the second day 4 c.c., the third day 5 c.c., and continued with this dose the following days. If no improvement was noted after ten injections had been given, he raised the dose to 6, 7, or even 8 c.c., and in one case he reached a maximum dose of 17 c.c., or about seventy centigrams of the cinnamate. The first sign of improvement noted was the subsidence of the fever, the second the return of the appetite, and then diminution of cough and expectoration. At the end of a month or two, the bacilli began to lessen in number, and by the end of three months they had usually disappeared entirely from the sputum. The average duration of treatment was four months; in a third of the cases the disappearance of the bacilli was not effected until the fifth or sixth month, but in another third it was complete by the end of one month or even earlier. The percentage of cures the author had obtained by this method employed exclusively was over eighty, but he would present no statistics, he said, his sole desire being to convince his hearers that cinnamate of sodium, used by his method, was curative of pulmonary tuberculosis The only deaths he had had were in patients suffering from very advanced gastrointestinal tuberculosis, and they were due rather to inanition than to the effects of the pulmonary lesions.

The Therapeutic Properties of Milk Serum.—Dr. R. Blondel of Paris presented a communication with this title. The serum of cow's milk, obtained by rapid coagulation at 38° C, effected by means of an acid, neutralization by soda, and filtration, was endowed, he said, with remarkable properties which seemed to have hitherto escaped general notice. One effect of the injection of this serum is a remarkable reduction of blood-pressure, more noticeable than that obtained by Trunecek's artificial serum, which renders the milk serum of great service in the treatment of arteriosclerosis. Another interesting effect is the reduction of temperature in specific fevers. In thirty cases of typhoid fever, pneumonia, tuberculous meningitis, and puerperal infection, the serum never once failed to reduce the temperature by from 2° to 4° C. This effect, the author believed, was obtained by a destruction of the toxins in the blood, and was not a specific action of a bactericidal character. In three cases of pneumonia, however, the reduction of temperature was immediate, and the improvement in the general and local signs of the disease dated from the injection of the serum. The injections of the milk serum were always well borne and never painful. The addition of a small quantity of sulphate of quinine (5 to 10 centigrams) seemed to increase the efficacy of the serum, a result which the author was inclined to attribute to the stimulating action of small doses of quinine upon the leucocytes. The usual dose employed was 20 c.c., given in two injections.

Nosography and Pathogenesis of Tuberculosis.—Dr. R. Balloto Taylor of Santander presented a very long memoir with this title, in which he advanced some novel, or at least unusual, views concerning the nature and in manner of propagation of this disease. Tuberculosis, he said, is a dimorphous disease, caused by the reaction of Koch's bacillus or of its toxins on the organism. This bacillus enters the organism in two different ways and in two different states, and upon these conditions depend the various clinical forms of the affection. When the bacillus is in mature form it can enter the system only through inoculation, in its embryonic form it is transmitted to the human embryo during the act of procreation. The clinical form due to inoculation of the mature bacillus is the granular, or acute generalized miliary tuberculosis; that resulting from hereditary transmission of the specific germ may be either pulmonary phthisis, tabes mesenterica, chronic cheesy degeneration of the lymphatic ganglia, bones, joints, or other organs or tissues. By reason of this duality of form and of etiology, this affection belongs to the inoculo-hereditary group, of which cancer and leprosy are the most noticeable other members. Inoculations productive of the acute miliary form may be made directly from man to man, and probably also through the instrumentality of flies, mosquitos, and other stinging insects, such as horseflies. Direct inoculation is, however, rarely productive of results, hence the comparative infrequency of this form of tuberculosis. In view of the fact that the pulmonary, mesenteric, lymphatic, and other chronic manifestations of tuberculosis are solely the consequence of the hereditary transmission of the parasite in an embryonic form, the inhalation of atmospheres more or less charged with tubercle bacilli, is absolutely innocuous, so far as the propagation of tuberculosis is concerned. Although some experiments have claimed to produce miliary tuberculosis in the lower animals by submitting them to the inhalation of air charged with tubercle bacilli, others have resorted to the same experiments with exactly opposite results, and moreover there is no authentic case on record of tuberculosis being transmitted to man in this way. For this reason the campaign recently instituted against indiscriminate expectoration by the phthisical must be futile; indeed, the inutility of this campaign has already been demonstrated by the fact that it is precisely in countries where the warfare is waged most vigorously that tuberculosis is most rife. It has been demonstrated also, time and again, that if the subjects of hereditary tuberculosis, that is to say those who carry within them the embryonic germs of tuberculosis received from their parents, avoid certain unhygienic factors, such as overwork, humidity, abuse of sunlight, and ventilation, alcoholism, etc., the germ may remain indefinitely in embyronic form, tuberculosis, therefore, never developing. The only prophylactic measures of proved efficacy are those looking to an improvement in the hygienic conditions surrounding the predisposed individual, that is to say, the one carrying within his tissues the embryonic germ. Tuberculosis, being essentially a disease transmitted by inheritance, it is improbable that it will ever be banished from the world. As a compensation for this, however, it is one of those affections the development of which can be the most easily prevented by proper measures. As a logical development of the peculiar views held by him, the author concluded with the following rules for the prevention of tuberculosis: Individuals of tuberculous stock should be most urgently advised never to marry. The erection of dwellings and workshops where dampness is likely to prevail, or to which air and sunlight have not free access, should be

forbidden by law. Delicate subjects of tuberculous parentage should not be allowed to take up any fatiguing or confining occupation. Duties on all the most nourishing and indispensable articles of food should be removed, while those on the less nourishing or noxious articles should be raised, those on strongly alcoholic beverages being almost prohibitive. In short, the prophylaxis of tuberculosis consists in raising to the highest pitch of excellence the social and hygienic conditions of the community, and especially in raising the physical well being and invigorating the organic soil already sown with the seeds of the disease.

Relation of Acute Bronchitis to Pulmonary Tuberculosis.—Dr. Léon Chauvain of Paris presented a paper in which he dealt with acute bronchitis in its relation with the several stages of pulmonary tuberculosis, as cause, effect, and complication of this disease. The essay was divided into three parts, treating severally of (1) Bronchitis premonitory of tuberculosis, preparing the soil for the reception and development of the tubercle bacilli; (2) Bronchitis occurring in the second stage of tuberculosis and caused by the presence of the tubercle bacilli, being thus an effect of the disease; (3) Bronchitis in the third or cavitary stage of pulmonary tuberculosis, being then a most formidable complication of the preexisting malady.

The Curability of Pulmonary Tuberculosis.—Dr. Juán Manuel Mariani of Madrid read a paper with this title, of which the following were the conclusions: (1) Pulmonary tuberculosis is curable. (2) The probability of its cure is greatest between the ages of thirty and fifty years. (3) The form in which the disease is circumscribed to one lobe of the lung, even when it is apical, a form which resembles closely surgical tuberculosis, can be cured in sixty cases out of a hundred. (4) The unilateral forms of gradual evolution unaccompanied by marked general disturbance, are relatively quite curable. (5) The diffuse infiltrated forms in adolescents, accompanied by pronounced febrile reaction, are incurable. (6) Hospital patients likewise are seldom cured, whatever may have been the initial form of their malady, for upon entering they are usually in the phthisical stage of the disease. (7) Tuberculosis in all its forms is, as a rule, curable only in the rich, since they alone are able to afford the great expense which the long course of treatment demanded by the disease entails.

The Nature of Rheumatism.—Dr. Vicente Roig é Ibáñez of Valencia read a paper on this subject in which he rejected entirely the microbic or infectious theory of rheumatism, holding on the contrary that the disease was caused by certain chemical combinations of uric acid. Rheumatism, he said, was due to the retention and decomposition of the complex salt of biurate and phosphate of sodium, the biurate possessing algesic properties varying in intensity directly with the amount of the salt present. The fever accompanying rheumatism was sometimes of infectious origin, constituting then a true complication of the disease, and sometimes it was caused by the action of the biurate of sodium on the vasomotor nerves. Finally, he contended, all the forms of rheumatism—acute, subacute, chronic, and muscular—rheumatoid arthritis, and even gout, were simply varieties of one and the same disease, all having a common origin.

The Diagnosis of Rabies in the Dog.—Dr. Dalmacio Garcia of Madrid read a paper on this subject, of which the following were the conclusions: (1) Whenever, in making an autopsy on the body of a dog dead of a suspicious disease, one finds a number of foreign bodies in the stomach, together with a small quantity of blackish liquid, the mucous membrane of the stomach and duodenum being dotted and streaked with ecchymoses, a diagnosis of rabies is justifiable. The absence of these signs, however, furnishes no proof of the non-existence of this affection. (2) The presence of sugar in the urine adds to the probability of the disease having been rabies, and the absence of glycosuria affords a certain, though not absolute, presumption against rabies. (3) The histological lesions noted by Balzer, Benedikt, Golgi, and especially Babès, when they are clearly present, possess a very great diagnostic value, and indeed establish a diagnosis of rabies. But their absence does not warrant the contrary assumption, since they have sometimes been wanting in dogs dead of undoubted hydrophobia. (4) The ganglionic lesions described by Nelis and Van Gehuchten, when typical, are pathognomonic, especially in dogs under ten years of age. (5) The cellular lesions noted by Ehrlich are of very slight diagnostic value. (6) Lesions of the salivary glands are not of such diagnostic importance as those of the neuraxons and of the cerebrospinal ganglia. (7) Polynucleosis, although of undoubted diagnostic value, is a less certain sign than the nervous lesions. Nevertheless, whenever possible, its presence or absence, as well as that of glycosuria, should be determined.

Analgesia by Pure Oxygen.—Dr. José Codina Castelví of Madrid presented a communication on the use of oxygen as an analgesic. The gas was given by hypodermic injection. As a rule the analgesia was limited to a rather wide zone surrounding the point of injection, though sometimes it extended to the terminal filaments of the nerves passing through the region of the injection. The analgesia was always rapid in its appearance, the pain beginning to diminish in from five to thirty minutes after the injection of the gas, and often lasted for from twenty-four to forty-eight hours without any repetition of the treatment. The injection should be made preferably at the point of emergence on the skin of the nerve, but it might almost equally as well be made in any part of the painful region. The dose varied between 200 and 100 c.c. of pure oxygen, being in general proportioned to the intensity and duration of the pain. The procedure caused no pain, and several injections could be made at different points at the same sitting in case of disseminated or very severe pain. The analgesic effect obtained might be attributed chiefly to the chemical action of the oxygen, though the author was not in position to say in what this action consisted. He had obtained surprising results by this treatment in sciatica, in neuralgia of branches of the lumbar, cervical, and brachial plexuses, and in the pains of polyarthritis deformans; and it was reasonable to assume that a like success would follow the employment of this method in the treatment of intercostal or trigeminal neuralgia, the pains of herpes zoster, toothache, and the pains of chronic rheumatism and of various nervous diseases, and even those of superficial cancer.

Infectious Endocarditis Successfully Treated by the Rectal Injection of Antistreptococcus Serum.—Sir Dyce Duckworth of London reported the case of a boy, fifteen years old, who was admitted to hospital complaining of generalized pains and presenting over the entire body an eruption resembling a polymorphous erythema. The disease had begun two days before with a series of chills followed by fever. There was no evident cardiac lesion, but a systolic murmur was audible at the apex. Later there was a hydrasthrosis of the knee and several other joints became more or less painful. There was no sign of splenic or renal infection. The fever was very high with daily ascents, and chills occurred at irregular intervals. Treatment by sodium salicylate, quinine, oil of wintergreen, and calomel afforded no relief, and yeast given in large doses for several days as well as two subcutaneous injections of 10 c.c. each of antistreptococcus serum were equally unproductive of results. It was then decided to give the antistreptococcus serum in 10 c.c. doses by rectal injection. Within two days a remarkable amelioration of all the symptoms set in and continued without break. The fever subsided in two weeks, no new eruption appeared, but the cardiac murmur persisted. The injections were continued for a period of about five weeks. At the end of this time the boy was sent to the country, and returned in a couple of months perfectly

well and with normal heart sounds. The diagnosis was first of erythema multiforme consequent upon rheumatismal infection, but the gravity of the symptoms and the obstinacy of the disease showed that the case was one of serious septic infection. The improvement following the rectal injections was most marked, but whether it was due to them seemed questionable, since the author employed the same in a subsequent case of similar nature without any good result. Some of his colleagues, he said, were inclined to attribute the cure to the yeast, yet no amelioration was apparent until the rectal injections were begun.

Treatment of Catarrhal Jaundice.—Dr. P. Revidzoff of Moscow, in a communication on this subject, said that the ordinary duration of catarrhal jaundice was from two to six weeks—seldom less than two, but sometimes more than six. The remedies commonly employed were far from being always capable of rapidly cutting short the morbid process. The author had found much benefit to follow lavage of the stomach with hot water (about 100° F.). This acted as a true chologogue, inducing a flow of bile through the choledoch duct, as evidenced by the return of color to the stools. Immediately after the return of the bilious flow, the symptoms of the disease began to subside, and in from three to seven days, varying with the gravity of the case, a complete cure was obtained. The author resorted to none of the usual remedies, not even dieting his patients, relying entirely and exclusively on stomach washings.

Removal of Carbonic Acid from the Body by Alkaline Sugars.—Dr. Schücking of Pyrmont explained his method of extracting carbonic acid from the tissues, in cases of asphyxia, by means of subcutaneous or intravenous injections of alkaline sugars—the fructosate and saccharate of sodium (natrium fructosatum et natrium saccharatum). These alkaline sugars seize with avidity upon carbonic acid, splitting up into sugar and sodium carbonate. The author claimed priority in the use of these sugars, having employed them with success in 1893, three years before the experiments of Kuliabko were undertaken. Since that time the remedy had been applied by himself and others in many cases of asphyxia, collapse, extreme debility, hemorrhage, sepsis, and angina pectoris. In conclusion he reported two cases of asphyxia neonatorum, in which he injected a solution of the fructosate of sodium through the umbilical vein. No heart movement could be detected before the injection, but soon after the pulse could be felt, and in a few minutes the first inspiration was made. The solution employed by the author was one of 0.5 of sodium fructosate with the addition of sodium chloride.

The Diagnostic Value of Œsophagoscopy.—Dr. Hugo Starck of Heidelberg presented a communication with the following conclusions: (1) Œsophagoscopy is entirely practicable in the great majority of cases. (2) The best instrument to employ is the straight inflexible tube. (3) Œsophagoscopy is the most certain method of detecting and localizing foreign bodies. (4) An early diagnosis of cancer is possible only by means of an œsophagoscopical examination. (5) This is also the surest method for diagnosing anatomical lesions of the œsophagus, such as ulcers, cicatrices, inflammation, stenoses, etc. (6) A differential diagnosis between functional and organic strictures is often impossible without the use of the œsophagoscope.

Etiology of Bilious Hæmoglobinuric Fever.—Dr. Spiridion Kanellis of Athens, in a paper with this title, said this affection was encountered chiefly in marshy regions, the most frequent etiological factors being (1) malaria and (2) quinine. A knowledge of the causation was very necessary as a guide to the therapeutics of hæmoglobinuria, for in the first form quinine was indicated and should be given in large doses by subcutaneous injection. In most cases of purely malarial causation this remedy was marvelously efficacious. In the second form one must naturally abstain entirely from the use of quinine, the treatment consisting in absolute rest, a milk diet, and the use of acidulous drinks, such as lemonade. In cases of malarial hæmoglobinuria, sudden chilling of the body might act as an exciting cause. The mortality of the malarial form of blackwater fever following pernicious comatose malarial fever was about 20 per cent.

Chloroform in Typhoid Fever.—Dr. José Sureda Massanet of Artá, Balearic Islands, presented a communication in which he praised the virtues of chloroform in relieving many of the symptoms of typhoid fever through its action on the nervous system. It calmed the restlessness of the patient, producing a delightful sensation of placidity, and influenced favorably the course of the disease, often shortening its duration, preventing complications, avoiding relapses, facilitating assimilation, and accelerating convalescence. In 167 cases of typhoid fever, treated exclusively by potions of chloroform in one-per-cent. solution, the author had had a mortality of but 6 per cent. The remedy was always well borne, easy to administer, and never repugnant to the patient, even when given continuously for long periods. It should be given as a prophylactic of grave complications as well as a curative agent of those already developed. Besides its calming effect upon the nervous system chloroform acted as an internal disinfectant, destroying, or at least attenuating, the specific bacilli within the organism. The author suggested that the remedy might also prove an effective prophylactic in cases of exposure to typhoid infection, but this as well as other points could be determined only by further observation.

Treatment of Typhoid Fever.—Dr. Juán Manuel Mariani of Madrid discussed the question of diet and of hydrotherapy. Notwithstanding the organic losses in typhoid fever, he said, the patient could be sustained with milk, broth, and alcohol. The milk diet should be prolonged throughout the period of convalescence, its diuretic action favoring the elimination of the toxins of the disease. Indeed, no typhoid patient should take any solid or semi-solid food until at least a week after complete defervescence—that is to say, until the maximum axillary temperature had remained at 98.6° F. for eight days. If this rule were transgressed a relapse could almost with certainty be looked for. As to the question of hydrotherapy, he held that the tub-bath should not constitute a routine treatment of typhoid fever, its sole indications being hyperpyrexia and ataxia. The temperature of the bath should be from 86° to 90° F. when the patient enters it, the water then being gradually cooled to 80° or 76° F. Both hot baths and cold baths were injurious rather than beneficial in the treatment of typhoid fever, and in many cases, indeed, no indication whatever existed for a resort to hydrotherapy.

Educational Treatment of Ataxias.—Dr. Joaquín Decref of Madrid spoke of the value of the method of treating stammering by educating the muscles, as devised by Chervin in 1877 and applied by Frenkel in 1890 to cases of tabes dorsalis, and which had been employed by himself as early as 1886 in the treatment of chorea. His first experiences were with this disease, but they were so encouraging that he soon extended the method to other troubles of coördination and to affections resulting from long immobility of the muscles. He advised a resort to it in all cases of incoördination or ataxia, whether the cause could be determined or not.

Etiology and Prophylaxis of Malaria.—Drs. F. Huertas Barrero and Gustavo Pittaluga presented a very long communication with this title, in which they discussed the prevalence of the disease in the Iberian peninsular. The views expressed regarding the etiology and the counsels advised in the way of prophylaxis were those already expounded by English and Italian workers and well known to students of malaria.

SECTION ON OBSTETRICS AND GYNECOLOGY.

The Stump in Partial Hysterectomy.—Dr. L. G. Richelot of Paris, in a paper with this title, said that partial hysterectomy was a very good operation in certain cases, but the preference shown for it by some surgeons was not well founded. Total vaginal hysterectomy, when the lower segment of the uterus was free from fibroids, was neither more difficult nor more grave than the partial operation, the vaginal stump being formed as easily as the cervical one. In atypical and complicated cases, however, it might be more convenient to leave a pedicle, and in such cases only the partial operation might be preferable. After a partial operation there was danger of malignant degeneration of the stump, and when circumstances permitted of a choice of operations this fact should be taken into consideration, especially as there was really no great difference between the two procedures from the point of view of technique.

Treatment of a Mobile Retroflexed Uterus.—Dr. Adrian Schücking of Pyrmont described his experience in the treatment of this form of displacement. In eighteen cases he fixed the portio vaginalis and the posterior fornix by means of two circular sunken ligatures of silver wire, which he left in position for from four to six weeks. The results were good in nearly every case. In one case he made a paraffin injection into the anterior fornix with success, the paraffin mass taking the place of a Schultze's pessary.

Treatment of Placenta Prævia.—Dr. D. Draghiescu of Bucharest presented a table of 162 cases of this complication observed during a period of twenty-six years among 28,241 women, giving a percentage of frequency of 0.57. The treatment varied according to the period at which the hemorrhage occurred, whether during pregnancy, during labor proper, or during the expulsion of the after-birth. In cases of slight hemorrhage during period of gestation the best treatment consisted in vaginal injections of hot water and rest, with "armed expectation." When the hemorrhage was more profuse and persistent, it was necessary, to tampon the vagina, a procedure which usually brought on labor. During labor the treatment should vary according to the indications—very hot and prolonged vaginal injections, the vaginal tampon, rupture of the membranes, or podalic version and rapid dilatation of the cervix. Treatment of placenta prævia, after the birth of the child, was simply that of retained placenta in general—removal of the after-birth and clots, and possibly a tampon of the lower segment of the uterus. The author's favorite method of treatment was by the vaginal tampon; he employed it in 70 of his 162 cases, with a mortality of only 14.28 per cent. The total maternal mortality was but 21 out of 162, or 12.96 per cent.; the fetal mortality was 85 out 165 children, or 51.55 per cent.

Bilateral Extra-uterine Pregnancy.—Dr. A. Psaltoff of Smyrna reported this case. The woman, thirty-five years old, came under treatment for severe abdominal pain with distention. She gave a history of having had an attack of abdominal pain and tenderness three years before. This lasted with intermissions for five or six months, at the end of which time it disappeared, the menses which had ceased returned, and the woman resumed her usual occupations. Four months before coming under observation she was seized again with a similar attack of pain in the abdomen, vomiting, and suppression of the menses. A diagnosis of ectopic gestation was made, and an operation was determined upon. A cœliotomy being made, two fœtuses were found, one about five months old, in the right tube; the other, about four months old, mummified, in the left tube. The latter had evidently been the cause of the pain three years before, and had become encysted and mummified, ceasing then to give trouble. The author's conclusions, from a study of this case, were: (1) The fœtus in a case of extra-uterine pregnancy may remain several years in the abdominal cavity without causing any serious inconvenience to the mother. (2) A woman who has had an extra-uterine pregnancy is liable to another. (3) In operating on a case of extra-uterine pregnancy the surgeon ought always to make a careful examination of the opposite tube. (4) In order to prevent a second accident of the same nature, it might be advisable, when operating in a case of ectopic gestation, to remove the uterus and adnexa at the same time, if the woman's condition permitted.

Technique of Abdominal Hysterectomy.—Dr. J. L. Faure of Paris presented a communication on this subject. The operation of choice, he said, except in cases of cancer, was subtotal hysterectomy; this operation would be preferable, if for no other reason, because of the simplicity of hæmostasis as compared with that in total extirpation of the uterus. In every operation the surgeon should have clearly formulated in his mind the object to be aimed at, and should endeavor to reach the lower pole of the uterus and adnexa by the shortest and easiest route. Then, according to the indications present, a choice should be made between uterine decollation, Kelly's method—called in France the American method—Terrier's preliminary extirpation of the uterus, and uterine hemisection.

Treatment of Fibromata and Prevention of Neoplasms by Physicotheraphy.—Dr. J. Rivière of Paris advocated the employment of physicotherapy, or the combined action of electricity, heat, and light, in the treatment of uterine fibromata. Treatment by physical agencies, especially electricity, he held, restored local and general nutrition, reduced congestion, and was depurative in its action. It prevented benign tumors from degenerating into cancer, especially in the arthritic in whom malignant degeneration was most likely to occur. Electricity was one of the most useful of these physical agencies, but the author cautioned especially against the error of attempting to replace surgery by destructive electrotherapy.

The Pathogenesis and Treatment of Chronic Cellular and Peritoneal Inflammations of the Pelvis.—Dr. Ramón Martín Gil of Malaga presented this communication. The factors entering into the pathogenesis of these inflammations were, he said, cysts of the ovary, especially dermoids; septic infection of the uterus, resulting from unskilful manipulation of this organ; ligation of the pedicle of an ovarian tumor if the ligature was not absorbed or was not sterile; adhesions of the intestines, peritoneum, or epiploon to the ovaries or tubes; hæmatocele; ectopic gestation; finally and especially puerperal or gonococcal infection. The treatment was twofold: (1) The non-operative—hot injections, massage, the use of medicinal waters; (2) The surgical—section of Douglas's pouch, abdominal section, or Goffe's vaginal cœliotomy. The surgeon should never remove the uterus and ovaries so long as a hope, however slight, remains of preserving them.

Treatment of Urethrovaginal Fistula.—Dr. Candela of Valencia read a paper with this title, of which the following were the conclusions: (1) In order to relieve the troubles caused by a urethrovaginal fistula one should always endeavor to form an artificial urethra. (2) A preliminary colpocystotomy is absolutely necessary in order to ensure the adhesion of the freshened surfaces. (3) The result of this operation will depend upon the state of the tissues, the skill and delicacy with which the operation is performed, and the care exercised in the after-treatment. (4) Even though one cannot always give a favorable prognosis, an operation is the only thing which gives a hope of cure.

Conservative Surgery of the Uterine Adnexa.—Dr. M. A. Fargas of Barcelona read this paper. The preservation of the ovaries, or even a part, he said, exercised a very favorable effect upon the organism through the influence of the internal secretion of this organ and the maintenance of ovulation. The preservation of one tube, connected with the ovary, even if it is considerably altered in form, allowed of the possibility of subsequent pregnancies. The preservation of the tubes without ovaries would seem to serve no useful purpose. In cases of benign neoplasms of the ovary, the organ or a part of it

might be preserved by dissecting away the growth. In trophic affections of the adnexa it was almost always possible to preserve a portion of the ovary. In cases of infection a conservative operation was imperative whenever the nature of the lesions left a hope of anatomical and functional restoration. In such cases operation should be deferred until the lesions had reached their full development, and the infective process had run its course. A mutilation that was not demanded by the nature of the lesion was not justifiable for the sake merely of technique. The facility and safety of conservative operations were well established, yet the contraindications and limitations were numerous. The abdominal route was the best one when conservative operations were to be undertaken. Gynecology of the present day, while perfecting the technique and gaining a greater insight into the nature and origin of lesions of the uterine adnexa, must learn to be more respectful toward these organs and their functions than it was in the last quarter of the century just past.

Hysterectomy in the Treatment of Puerperal Infection.—Dr. Francisco de Cortejarena of Madrid presented a communication of which the following were the conclusions: (1) The uterus is often the main source of puerperal infection, by reason of the matters retained within its cavity, and in such cases the indication is, of course, to remove the infecting material. (2) A generalized infection of several organs, veins, kidneys, and even the blood, diminishes the importance of the uterus as the infecting agent, and in such case there is no indication for local intervention. (3) Owing to the great variation in the modes of infection, the treatment must vary, and should, above all, never be stereotyped. (4) Infection, even when long continued, may often be combated by medical and local non-operative treatment, in which case surgical measures are strongly contraindicated. (5) It is difficult to determine the most favorable time for surgical intervention, and one may readily be too precipitate or delay too long. (6) Hysterectomy is sometimes the only means of saving life in cases of continued infection proceeding from the uterus, but it is a measure of last resort, since it condemns the woman to sterility. (7) A bacteriological examination of the blood is of little service in determining a choice of therepeutic measures.

Indications for Hysterectomy in Beginning Acute Sepsis.—Dr. J. Cortiguera of Santander read a paper with the following conclusions: (1) With care in the institution of prophylactic measures puerperal infection should be of very infrequent occurrence. (2) Cleansing of the cavity of the uterus, when resorted to early and rigorously prosecuted, cuts short almost all cases of puerperal infection. (3) There are some exceptional cases in which hysterectomy is indicated, when the local measures employed have failed to cure the toxæmia. (4) Infections for which operation is chiefly indicated are those in which the lesions are temporarily limited to the uterus, the adnexa, and the pelvic peritoneum, but in which there is a probability of extension to the general peritoneum, or of the occurrence of general sepsis. (5) Before deciding upon a mutilating operation the surgeon must be certain that the source of the infection is not in the perineum or the vagina; that the infection is not a descending one through the blood circulation, independent of the uterus; and that no involvement of the defensive lymphatic glands has occurred. (6) A condition of collapse or of extreme physical depression may also contraindicate hysterectomy.

Treatment of Placenta Pravia.—By Prof. A. R. Simpson of Edinburgh. "The conditions under which a woman suffering from placenta prævia may be found are too diverse to permit one to formulate any system of treatment suitable for all cases." (1) In most cases the best treatment consists in bipolar version, a leg being seized and the child extracted slowly. (2) An expectant treatment may be adopted when hemorrhage occurs some weeks before the termination of pregnancy and when the loss of blood is not too great. However in such a case the medical attendant should visit the patient from time to time, and always be prepared to institute radical measures if necessary. (3) In some cases, especially in primiparæ, one should begin by vaginal tampons, or by the employment of a hydrostatic dilator introduced first into the vagina and then into the cervix. (4) In cases of marginal inplantation, when the orifice of the uterus is already half dilated, the placental lobules may be separated from the lower segment of the uterus by the finger. This manœuvre arrests the bleeding, and permits of the complete dilatation of the cervix by natural means without further loss of blood. (5) In all cases of placenta prævia, the third stage of labor should be carefully watched, and the accoucheur should be in readiness to combat hemorrhage during this stage, or even postpartum if necessary, by tamponning the cavity of the uterus.

ILLINOIS STATE MEDICAL SOCIETY.

Proceedings of the Fifty-third Annual Meeting, Held in Chicago, April 29 and 30, and May 1 and 2, 1903.

The society convened in Tremont Hall of the Northwestern University, under the presidency of Dr. M. L. Harris of Chicago.

Addresses of welcome were delivered by Dr. Taylor, prosecuting attorney of Chicago; Hon. Henry G. Foreman, President of the County Commissioners, and by Dr. James H. Stowell.

The response to these addresses was made by Dr M. L. Harris, the President.

President's Address.—President Harris, in his address, stated, among other things, that success, as applied to the life of the physician, meant something else than his own opinion of himself. It meant the realization by others of the value of his labors, of their value, not simply from a commercial standpoint, but from the standpoint of the scientist and the humanitarian, to others of his knowledge and skill. That natural aptitude and ability count for something in determining the degree of success to which an individual may attain must be granted, as it is a common observation in all walks of life, that some individuals, with scarcely any opportunities in early life, have struggled to the top, over almost insuperable obstacles; notwithstanding this fact, the scientific child study which so many are now vigorously prosecuting, with such rich rewards for their labor, demonstrates clearly that much of the dulness, the apparent stupidity and lack of capacity to learn in the early years of life were closely related to, if not dependent on, certain physical defects, and that many of these defects and the capacity to learn had, in a broad sense, a nutritional basis.

He recapitulated, briefly, the factors which contribute most to the scientific success of the physician, namely, first, a thorough knowledge of the rules of logic and the theory of reasoning, in order that the physician might be able to deduce warrantable conclusions from the evidence at hand. Second, the physician must train his powers of observation, in order to present to his reasoning faculties correct data. Third, he must be familiar with what is known on the subject before him, in order that he may correlate his own observations with the facts presented by others.

Approximately, seventy papers were read before the three sections, and three general addresses delivered.

We present abstracts of the more interesting papers.

The Dangers of Exclusive Milk Diet in Nephritis.—Dr. A. C. Croftan of Chicago read a paper with this title. The popular prejudice in favor of an exclusive milk diet in nephritis, and the fundamental fallacies of this prejudice, were pointed out The three indications for

dietetic treatment of nephritis were: (1) Protection of the secreting epithelium of the kidney; (2) protection of the cardiovascular apparatus; (3) protection of the general nutrition of the patient. The author presented reasons why an exclusive milk diet met none of these requirements. The best substitute for an exclusive milk diet, as deducted from modern investigations into the causes of nephritis and the excretion of urinary solids in inflammatory diseases of the kidneys, was pointed out.

The Breast Versus the Bottle in Infant Feeding.—The author of this paper, Dr. ALFRED C. COTTON of Chicago, compared the mortality statistics of natural and artificial feeding. He referred to the relative morbidity attending each method. Human milk was compared with that of other mammals. He pointed out the dangers of the acceptance of even the best known methods of artificial feeding. The more nearly perfect the food laboratory, the greater were the possibilities of harm from overconfidence in artificial methods. Infants were too frequently denied the breast for trivial and insufficient reasons. In view of our knowledge of the morbidity and mortality of artificially fed infants, what right had physicians needlessly to expose any infant to such chances? He made a plea for the establishment of a bureau of information and supervision, to facilitate the procuring of wet nurses when required.

Cockroaches as Typhoid Infection Carriers.—Dr. ROSA ENGELMANN of Chicago discussed this subject under the following heads: (1) Vermin as active intermediary hosts of various infections; (2) history of a house epidemic of typhoid fever; (3) cockroaches; sewage and water denizens not heretofore classed as typhoid-infection carriers; (4) need of examination and cultures from intestinal contents and from feet of cockroaches for pathogenic germs—especially the Eberth bacillus; (5) opportunity the coming summer (after necessarily prolonged rainfall) for such work in the vermin-infested slums of Chicago.

Hysteria.—Dr. HUGH PATRICK of Chicago reported cases of hysterical paraplegia, hysterical amblyopia with rigid pupil, hysterical anorexia, hysterical pseudomeningitis, and hysterical deaf-mutism.

The Treatment of Some of the Degenerations of the Cerebrospinal Apparatus, with Particular Reference to Optic Atrophy.—Dr. ARCHIBALD CHURCH of Chicago said that the general feeling was that degenerations taking place in the conducting tracts of the cord, as in locomotor ataxia and atrophy of the optic nerve, arising from any cause, as well as the changes in the brain and cord that are found in paretic dementia, are quite unamenable to treatment. In all of these conditions the tendency to remission was, in itself, a confusing element, in judging the therapeutic value of any line of treatment. In the case of the optic nerve, the ophthalmoscope enabled the physician accurately to see changes which were taking place, and by appropriate tests variations for better or worse could be actively determined and systematically recorded. A number of cases of optic atrophy associated with a secondary syphilis had been under observation for from two to ten years, and were made the basis of an estimate of the value of mercury in controlling these degenerations.

Ophthalmoscopic examinations and perimetric records made in these cases by competent oculists demonstrate that in some instances degenerations in the optic nerve could be distinctly controlled. Other cases of locomotor ataxia and paretic dementia were adduced, in which the clinical records indicate a similar retarding influence upon the processes of degeneration in the brain and cord.

Euphthalmin, as a Mydriatic for the General Practitioner.—Dr. ALBERT B. HALES of Chicago read a paper with this title. He said that the use of the ophthalmoscope was becoming more general in medical diagnosis. He pointed out the need of a drug to dilate the pupil, not only to study the condition of the fundus, but also to note the condition of the cornea, iris, and lens. Atropine was too powerful, and destroyed accommodation. Homatropine was of only less strength, and was expensive. Cocaine was good, but dangerous to the eye. Euphthalmic scarcely affected accommodation; it dilated the pupil fully, and in a short time. It had no dangerous element about it, and its effect passed quickly away. He detailed experiments.

Abdominal Pain in Pleurisy and Pneumonia.—Dr. JAMES B. HERRICK of Chicago said that pain in pleurisy and pneumonia might be referred not only to the affected side of the chest, but to the opposite side of the abdomen. In the latter case, abdominal disease, for example, appendicitis, might be simulated. He dwelt upon the importance of recognizing the thoracic organ of pain, as it might thus prevent surgical interference. Illustrative cases were reported. The anatomical basis for the referred pain was found chiefly in the course and distribution of the intercostal nerves. The diagnosis was generally easy when once the possibility of the thoracic cause for the abdominal pain was thought of, and a careful examination of the chest made.

Some Unusual Cases of Chorea.—Dr. L. HARRISON METTLER of Chicago reported a few peculiar cases of chorea. He advanced the idea that chorea was a symptom and not a disease; that its etiology was not so obscure as it appeared to be; that it had some remarkable frequently overlooked features in its symptomatology, and that its treatment was varied and deserving of more careful study.

The Secondary Results of Cardiac Disease.—Dr. JOHN A. ROBINSON of Chicago reported a unique case. He discussed the various valvular lesions and their pathological sequence, myocarditis, and the secondary symptoms. He related a case of mitral insufficiency, with ruptured compensation, dropsy, and proliferative inflammation of the skin, with return of compensation and disappearance of the secondary symptoms. The entire circle of invalidism in this case lasted two years.

The General Practitioner and His Relation to Early Surgical Operations.—Dr. E. B. MONTGOMERY of Quincy called attention to the fact that the internists were too often apt to be influenced by the law opinion that surgical operations were only to be done as a last resort, and unconsciously lent themselves to delay in a large class of cases that should have surgical intervention early in their course. He contended that the unfavorable results which were shown to follow in too large a percentage of cases of carcinoma of the breast and uterus, were due to late operation. Appreciating this, the general practitioner should encourage among his patrons immediate consultation of the physician concerning every trouble with the breast in women, however insignificant, or any irregular hemorrhage, occurring after the age of forty years, and, if there was the slightest question concerning the presence of malignant disease, a surgeon should be associated with him in the case. In the author's opinion, the same rules should obtain in typhoid fever, with any evidence of perforation; in appendicitis; in cholecystitis with enlargement of the gall-bladder, and in enlargement of the prostate gland after the catheter life has begun; in pleuritic effusions lasting over two weeks, either purulent or not, and in hypertrophic cirrhosis of the liver, the early presence of the surgeon was advocated. In support of these opinions, facts and cases were adduced.

The Traction Injury of Arteries.—In a paper on this subject, Dr. S. M. WYLIE of Paxton said that normal nutrition and vascularization of the extremities depended upon an unobstructed flow of normal blood. Stagnation, partial or complete, favored the formation of fibrinous clots. Traction injuries of the arteries, by disturbing the

normal relation and function of the various coats, favored the formation of thrombus in two ways: (1) The ruptured walls of the interna curling up in the lumen act as an obstructant to the current; (2) the loss of contractile power from the overstretched or torn muscular fibers favored stagnation, and arrested the flow. Both were factors in the function of occlusion thrombi causing complete arrest of the circulation and subsequent death of the part. This was a surgical accident often overlooked at the time of the first dressing of an injured extremity, and when subsequent gangrene ensued, as it often did, it was attributed to faulty methods of applying the dressing.

Modern Surgery of Congenital Cleft Palate.—Dr. S. R. HOPKINS of Springfield presented a paper with this title, in which he spoke of the history and evolution of the operation. He gave a description of the uranoplastic operation in its infancy, and its advantages over later operations, with the statistics furnished by different operators. He likewise gave a description of staphylorrhaphy in later life; also made remarks on the power of speech following operations. He recommended a change from the usual *modus operandi* of closing continuous clefts in children over six months of age, with a report of two cases illustrating the proposed method.

Successful Removal of a Cystic Fibromyoma of the Uterus Weighing Eighty-seven Pounds.—Dr. J. CLARENCE WEBSTER of Chicago reported this interesting case. The patient was forty-one years of age; married. The tumor was of ten years' duration. The measurements were: Greatest girth of abdomen, five feet; the lowermost portion of the pendulous abdomen, eleven inches below the level of the anterior superior iliac spine. Operation was performed December 16, 1902. The abdomen was opened after Schleich infiltration of the skin. The separation of adhesions and ligation of the vessels were carried out during one hour, without any general anæsthetic. During another hour and a half only six ounces of chloroform were used. A panhysterectomy was performed, followed by a normal recovery.

The Treatment and the Causes of Death in Placenta Prævia.—The essayist, Dr. P. M. BURKE of La Salle, pointed out that the cause of death in placenta prævia was extensive rupture of the uterus, and not hemorrhage due to a mere separation of the placenta in the act of turning, as was popularly believed. Out of nine cases in all of which he turned, there were four extensive ruptures. Three of the patients died, and one recovered immediately after repairing the injury. The cause of death applied to the mother, as the cause of death of the child was self-evident. The only deaths were in the ruptured cases unrepaired. The lack of knowledge was due to small individual experience, consequent on the infrequency of such cases. In numerous cases of turning, in about a thousand cases of obstetrics, he never had had a rupture except in placenta prævia. The occurrence of rupture in these cases was not a coincidence, but due to the friable, brittle condition of the lower segment of the uterus. The treatment was surgical operation, prompt, heroic, and successful repair of the rupture.

Tuberculosis of the Vestibule of the Female Genitals.—Dr. J. H. STEALY of Freeport read a paper on this subject, in which he reviewed the cases in literature. He referred to the rarity of the lesion; the possible cause of the unfavorable course taken by the disease in this region; the difficulties attending the determination of whether the lesion was primary or secondary, and its bearing on the prognosis. He said the tuberculin test was the only accurate method.

Bloomington was selected as the place for holding the next annual meeting.

PERFORATING GASTRIC AND DUODENAL ULCERS: UNILATERAL EXCLUSION OF DUODENUM FOR PERFORATING ULCERS OF ITS POSTERIOR WALL.*

By ALBERT A. BERG, M.D.,
ADJUNCT SURGEON, MT. SINAI HOSPITAL,
NEW YORK.

PERFORATION of ulcerative processes of the stomach and intestines constitutes their most serious complication. Its occurrence means to the patient all the dangers of a local or diffuse infection of the peritoneum, if not immediate death from collapse. Especially significant are such perforations of benign ulcers of the upper part of the digestive tract. Their occurrence at once changes the rosy outlook for a spontaneous cure; the patient's life is cast into the gravest jeopardy, from which only the acute diagnostic acumen and the promptest action of his attending physician can help to save him.

The writer does not intend in this communication to enter into the etiology, pathogenesis, and symptomatology of gastric and duodenal ulcers; but will confine his considerations to their perforation; its result, its symptomatology, the question of surgical interference, and the results of operation with especial reference to the nature of the operation.

Results of Perforation.—These depend upon two factors: (*a*) The rapidity with which the ulcerative process extends through the walls of the stomach or duodenum, and (*b*) the site of the ulcer. It is very evident that when the ulceration spreads rapidly through the coats of the viscus, adhesive barriers with neighboring organs will less likely be formed and extravasation of the gastric and duodenal contents will very probably take place at the time of perforation. The location of the ulcer determines the character, extent, and site of the lesions that follow upon its perforation. If it is on the anterior wall of the stomach or duodenum extravasation into the free peritoneal cavity usually occurs; if on the lesser curvature or posterior gastric wall, spilling of the intestinal contents is likely to be limited to the bursa omentalis, and if on the posterior duodenal wall it will probably be confined to the cellular tissue behind the viscus, the ascending colon and perinephritic space. The location of the extravasation thus affords at once, upon opening the abdominal cavity, information as to the probable site of the ulcer; an important time-saving consideration.

When extravasation occurs into the free peritoneal cavity septic peritonitis ensues; the extent of this depends entirely upon the time that elapses between the onset of perforation and the time operative interference is undertaken. It is well to remember in this connection that the transverse colon, and mesocolon, may and usually do for a number of hours, limit the extravasation to the upper half of the peritoneal cavity; but that eventually the intestinal contents make their way downward along the ascending or descending colon, to the lower half of the peritoneal cavity. This natural limitation of the extravasation for a number of hours affords a slightly better prognosis from early operative interference to gastric and duodenal perforations than that which attends perforating ulcers of the small intestines, where no natural barriers to the rapid extension of the peritonitis exists. It also affords us an extra few hours time in which fully to substantiate our diagnosis without subjecting the patient to any increased danger. It is also worthy of note that the peritonitis caused by the extravasation of gastric or duodenal contents is likely to be of less virulent character than that which follows the spilling of contents from the lower part of the intestinal tract.

When the extravasation is into the lesser peritoneal cavity, or (bursa omentalis) its spread into the general cavity is usually prevented by adhesions, which close the Foramen of Winslow. A localized exudate into the retrogastric space results. Its extent varies; at times it spreads upward to the liver and diaphragm, invading one or both subphrenic spaces (and forming a subphrenic abcess), again it remains confined to the bursa omentalis, being limited below by the transverse colon and pancreas, or again it extends laterally to the region of the spleen, the perisplenic abscess (see history Sarah F., page 887).

When the extravasation has occurred into the retro-duodenal cellular tissue it there gives rise to abscess formation which spreads downward behind the ascending colon even into the pelvis and around the kidney (see history of Case III).

Such localized abscesses and peritoneal exudates, unless they are removed by operation tend to spontaneous evacuation by opening into some neighboring viscus or cavity, thus into the pleura, pericardium, colon, gall-bladder, or into the stomach and duodenum itself (see Autopsy of case III.), or upon the external surface of the body.

Of the results of perforation the writer has considered only the lesions due to the extravasation of infected stomach or duodenal contents. The lesions of neighboring viscera, *e. g.* the liver, pancreas, etc., which by adhesion to the floor of a slowly advancing ulceration prevented extravasation, but from contiguity themselves became involved in the ulcerative process, have not been mentioned, though the necrosis or abscess formation that may form in such viscera from this cause are of much importance.

Symptomatology of Perforation.—It is important clearly to differentiate between the cases in which extravasation accompanies the perforation, and those in which this does not occur, because of previous adhesions of the floor of the ulcer to neighboring parts. While we may, in the latter instance, correctly speak of a perforation of the stomach or duodenum, it is not attended for the moment by any new symptoms. The distant results, such as

*Read before Greater New York Medical Association.

necrosis of or abscess in these adherent structures do not concern us at this time.

In the first group of cases the entire symptoms are due to the extravasation. Their primal intensity depends on the extent and rapidity of the escape of intestinal contents, and their subsequent manifestations are proportional to the severity and extent of the septic peritonitis or cellulitis, the extravasation gives rise to.

Symptoms Prior to Perforation.—It is extremely doubtful whether there are any symptoms additional to those afforded by the ulcer *per se*, that attend the period just before perforation. In our cases there were no indications prior to the rupture that would lead to the suspicion of such an impending event. In one of the duodenal cases (Case IV), there had been no symptoms of the existence of an ulcer prior to the time of its perforation. In the other duodenal case there had been an attack presumably of catarrhal appendicitis lasting a few hours, several weeks before the perforation occurred. In one of the two gastric cases, the patient had been under treatment for some time, but had given no indications of impending perforation. The second case of our list was in the hospital at the time of perforation. She had received no food by mouth for a week, and seemed to be doing well until the perforation occurred. In her there was no increased leucocytosis. A study of the recorded cases in literature further substantiates the fact that there are no symptoms prior to perforation. The patients have either given no previous indications of the presence of an ulcer in the stomach or duodenum, or have suffered for varying periods of time from the usual manifestations of ulceration of these viscera. In the former the perforation with its subsequent train of symptoms has been the first indication of an ulcer; in the latter the perforation has occurred either at a time when the patients were suffering with an aggravation of their usual symptoms, *e. g.* in form of a hemorrhage, increased pain or vomiting (see history of Case II), or during an apparently quiescent stage of the disease. (See history of Case I).

Symptoms at Time of Perforation.—It is a mistake to think that all patients with perforation of any part of the gastrointestinal tract suffer at the time of its occurrence with collapse. The depression of the central nervous system may be entirely absent, *e. g.* in our cases II, III, and IV. The collapse is entirely dependent upon the extravasation, and not upon the perforation *per se*. It is not in evidence where extravasation is prevented by adhesion of neighboring parts to the floor of the ulcer. The writer has called attention to this in a previous communication on "Ruptured Typhoid Ulcers."*

Where the extravasation is slight or very slow, the symptoms of collapse may be entirely wanting, whereas, where the spilling is abundant and rapid, the central depression is very much in evidence, and death may ensue from the shock. The degree of collapse is entirely proportional to the amount of and the suddenness with which the peritoneal cavity is soiled by the infectious gastric or duodenal contents. Severe tearing pain in the epigastric and hypochondriac regions usually attends the rupture of the ulcer. Vomiting, hæmatemesis, may or may not occur; they are due to the ulcer rather than to its perforation.

Locally: The abdominal wall is motionless with respiration, and rigid—two very important signs of peritoneal inflammation.

*Medical Record, March 23, 1901.

The percussion note over the liver and spleen varies. If a perforation, with the escape of gas, into the free peritoneal cavity has taken place, superficial percussion over these organs is tympanitic. With small perforations and limited escape of gas, the percussion note over these viscera will not vary much from the normal. If the perforation is on the posterior wall of the stomach, gas may escape into the free peritoneal cavity with obliteration of liver flatness, if Winslow's foramen is open; this is, however, unusual. With perforation on the posterior wall of the descending duodenum, there is no escape of gas into the general cavity, and consequently no obliteration of liver or splenic dulness. (See history of Case III).

Palpation reveals a marked tenderness in the epigastric or hypochondriac regions; possibly a more or less extensive tumefaction. The latter is due either to the ulcer itself or to a localized extravasation around it. Over such a tumefaction the percussion note is dull tympanitic.

Leucocytosis.—Case II (observed at the time of rupture) showed no leucocytosis, although a gradually rising leucocyte count was observed in the course of the next twelve hours. In Murphy's case of perforated duodenal ulcer there was a high leucocyte count, six hours after the perforation. Our other three cases were admitted to the hospital at least twenty-four hours after the rupture had occurred, and were at the time of their admission suffering with diffuse peritonitis, which accounted for their hyperleucocytosis.

Symptoms Subsequent to Perforation with Extravasation.—They are those of an advancing septic peritonitis, with or without obliteration of liver dulness, depending upon the site of the perforation, or those of a retroperitoneal abscess on the right side of the abdomen:

Summary of Symptoms.—The ulcer may have been a latent one, and the perforation is the first indica- of its existence (especially is this the case in duodenal ulcers), or it may have given rise to the usual train of symptoms, and the perforation occurs suddenly during a period of exacerbation, or during its ordinary course. At the time of perforation there is usually a severe tearing pain in the epigastric or hypochondriac regions, accompanied or not with collapse and prostration.

Locally: The upper half of the abdominal wall is rigid, and does not participate in respiratory movements. There is distinct local pain and tenderness in the epigastrium, or hypochondrium, possibly a tumefaction.

Liver: Flatness on superficial percussion may or may not be obliterated. Vomiting and hæmatemesis may occur. Hyperleucocytosis has not been noticed in the reported cases.

Several hours after perforation the signs of septic peritonitis supervene and obscure all the other symptoms. The liver flatness may or may not during this later period be obliterated. If the perforation is on the posterior duodenal wall the patient goes on to develop a retroperitoneal abscess on the right side of the abdomen.

Question of Operation in Perforated Ulcers of the Stomach and Duodenum.—There can be very little doubt as to the propriety of surgical interference in perforating ulcers of the stomach and duodenum. The claim may possibly be made that by adhesion to neighboring viscera, or the abdominal parieties, closure of the perforation could be effected and extravasation prevented. However possible this is in the case of perforations of the small intestines, it is highly improbable, nay, almost impossible, in the case of the stomach and duodenum. For it is

to be noted that the small intestine is surrounded by freely movable coils of intestines and omentum, which can easily adapt themselves to the orifice of a ruptured ulcer, and so effectually close it. The stomach and duodenum, on the other hand, are in the vicinity of the liver and pancreas, organs more or less fixed and of firm consistency, which renders them less adaptable to close the irregular orifice of a ruptured ulcer. Where the liver and pancreas are found adherent to and forming the floor of an ulcer in the stomach or duodenum, such adhesion has occurred before rupture. It can be accepted without the shadow of a doubt that all those cases in which perforation into the general peritoneal cavity occurs, and some of those in which the rupture is into the bursa omentalis, develop diffuse septic peritonitis; and that the remaining cases in which the perforation is into the lesser sac, and those in which it is into the retroduodenal tissues, develop gas containing abscesses at the site of perforation.

Surgery has accomplished good results in these perforating ulcers, and promises to do even better with earlier diagnoses and improved methods of dealing with the coexisting peritonitis. Bolton Carter collected 59 published cases (Murphy, Perforating Duodenal Ulcers) of perforating duodenal ulcers. Of these 27 died without operation, the lesion being found post mortem. Of the remaining 32 subjected to operation 11 recovered, or 34 per cent.; Lenander states that the statistics so far published (1898) show that one-fourth to one-third of the perforating ulcers of the stomach and duodenum are saved by operation, and that the prognosis depends on the length of time that elapses before operation is undertaken, and on the extent and character of the peritonitis.

Time in Which to Operate.—The statement of Lenander just quoted, at once brings up the question, as to what is the best time for surgical interference: In this respect the cases may be roughly divided into two groups: (*a*) those that present the symptoms of perforation and extravasation into the free peritoneal cavity, and (*b*) those in which there are evidences of perforation *e.g.* severe tearing pain, shock, local abdominal rigidity, but no obliteration of liver or splenic dulness. The writer lays great stress upon the presence of gas in the free peritoneal cavity evidenced by a partial or complete obliteration of liver or splenic dulness or both, as an indication of the rupture and extravasation of the contents of a hollow viscus into the free peritoneal cavity. It has been his experience, gained from the observation of about twenty cases, that obliteration of liver and splenic dulness, always attended a rupture into the free peritoneal cavity; and that where the liver and splenic dulness and flatness were normal, the extravasation was always localized by adhesion of the ruptured viscus to neighboring parts.

In the first group of cases, we have every reason to assume that septic peritonitis will rapidly follow the extravasation, and, as would be expected, the prognosis would depend upon how soon after the rupture of ulcer the abdomen is opened and the perforation closed. Broadly speaking, this operation should be made as soon as a diagnosis is established. Though this waiting until a diagnosis is made, will at times entail the risks of a diffuse peritonitis, for the symptoms may be so indefinite as to forbid an early diagnosis being made, the writer feels that exploratory laparotomy for supposed perforation will neither rebound to the credit of the surgeon or to the benefit of the patient. Even with all the modern attention to asepsis and antisepsis, exploratory laparotomy has its mortality, and the surgeon and physician should rather tend to perfect their diagnostic acumen than resort to exploratory laparotomy for establishing a diagnosis.

In the second group of cases, viz., those in which with the symptoms of perforation there is no gas in the free peritoneal cavity, the question may very properly be raised, whether it would be advisable to wait before proceeding to operation. Though the urgency in these cases is not so immediate as in the preceding group, there is very little doubt that these patients should also be laparotomized, and the perforation closed if possible. It may be advisable in some of these patients to wait for a few days, permitting firm adhesions to form around the local extravasation; but, operation should not be too long deferred. For while isolated instances of spontaneous cure of a perforation and localized exudate do occur, the risks of septicæmia and pyæmia from an undrained septic focus, or those of secondary rupture of the septic material into the peritoneum, pleuræ, or pericardium, certainly excel those of an early operation.

Reports of cases show that sooner or later such localized exudates make their way into the subphrenic spaces, and unless evacuated and drained, rupture through the diaphragm, into the pleuræ or lungs. The question resolves itself thus: Will we operate under favorable conditions with a localized exudate and the good possibility of being able to close the perforation, or wait until a huge abscess has formed, and the patient has become septic and exhausted, and in whom a closure of the perforation is entirely out of the question. The history of the following case, operated upon by Dr. Gerster at the Mt. Sinai Hospital, illustrates this point:

(Mt. Sinai Hospital Reports, Vol. I, page 178): *Ruptured Ulcer on Posterior Wall of Stomach; Enormous Abscess in Retrogastric and Left Subphrenic Spaces; Thrombosis of Splenic Vein; Necrosis of Spleen and Lung Aspiration; Incision by Pleural Route; gastric Fistula, Sepsis, Inanition, Death.*—Sarah F., thirty-three years of age, was referred to Dr. Gerster by Dr. Strauss of New York. She had an old history of gastric ulcer for which she had been under medical treatment. Seven weeks before her admission to Mt. Sinai Hospital, she experienced a sudden pain in the umbilical region; since then she had continuous fever; no chills; vomited intensely fetid matter. On left side increasing dulness, extending from the sixth space posteriorly to the lower border of the ribs, apparently due to a tumor mass in the left hypochondrium. Occasionally after vomiting of fetid matter, the dulness was replaced by tympanitic resonance with succussion. Liver dulness, normal. Puncture in eighth left intercostal space yielded material of same appearance and odor as vomitus, containing particles of food. June 24, operation. Seventh and eighth ribs resected in axillary lines. Pleural cavity walled off by packings; diaphragm incised, and a large cavity opened into, situated in retrogastric space; its upper anterior wall formed by a gangrenous part of spleen, its anterior wall formed by posterior part of stomach, and communicating by an opening through the diaphragm with an abscess cavity in the lung. The cavity was filled with fluid having a peculiar methyl alcohol odor. The gangrenous portion of the spleen was easily removed. At the bottom of the cavity was seen a large gastric fistula, which could not be repaired on acount of the necrotic condition of the surrounding parts. Cavity evacuated and drained. Fistula plugged. June 25,

profuse discharge of material from stomach, and necrotic tissues of the walls of the cavity. Posture did not affect gastric discharge. July 1, death from inanition and sepsis.

Post-mortem: Perforation about six centimeters in diameter, in posterior wall of the stomach. Along the edge of the ulcer, a branch of the splenic vein is thrombosed and occluded. Spleen gangrenous in its upper part; a large infarct at the lower edge of the gangrenous area. Left lobe of liver contains a large abscess. Left lung gangrenous at its lower part.

The writer wishes again to direct attention to the percussion note over the liver and spleen in cases of rupture of any hollow viscus. Partial or complete obliteration of the dulness indicates extravasation into the free peritoneal cavity, and should decide us to immediate operation; normal dulness and flatness over these organs, points to a localization of the extravasated gas and intestinal contents; and while it may at times be advisable to wait for a few days until firm adhesions form around the extravasated material, operation is to be performed as soon as possible.

In cases of retroduodenal perforation, operation should also be done early. The dangers of delay are well shown in our Case III, where though the abscess perforated into the colon, the septic symptoms persisted, and so exhausted the patient that nothing further than incision and drainage of the abscess cavity could be done.

As to shock influencing the time for operation. The depression of the central nervous system is due to the extravasation, and the surest way to relieve it is to prevent further soiling of the peritoneum. Vigorous hypodermic stimulation and subcutaneous infusion will usually suffice to temporarily counteract the shock and enable the surgeon to proceed with immediate operation.

Prognosis.—The prognosis after operation depends upon several factors, chief of which are (*a*) the length of time that has elapsed before the operation is closed, for the severity and extent of the peritonitis is usually in direct proportion to the duration and extent of the extravasation, and (*b*) the emptiness or fulness of the stomach and duodenum at the time of perforation. Generally speaking, the peritonitis following gastric or duodenal rupture is less intensely virulent than that following perforation of the small intestine in its lower segments.

(*a*) *Operative Treatment of Ruptured Ulcers Situated on the Anterior Wall of the Stomach and Duodenum.*—As these are very accessible, their closure can as a rule be easily effected.

It is an important question how we should deal with the ruptured ulcer.

Excision of the necrotic edges or excision of the entire ulcer, and then closure of the defect by suture has not yielded as satisfactory results as simple inversion by suture of the ulcer into the lumen of the viscus. This may necessitate a considerable infolding of the wall of the stomach or duodenum; in the case of the former such infolding is of no material import; in the duodenum it may so materially narrow the lumen of the viscus, as to necessitate its exclusion by gastroenterostomy. It has been the experience of the writer that a reduction in the diameter of the lumen of any part of the small intestine to one-half the normal, does not result in any marked interference with the passage of contents through it. Reperforation after inversion of the ulcer is not likely, provided the inverting sutures are passed through healthy tissues.

The advisability of performing gastroenterostomy at the same sitting, with the idea of aiding in the healing of the ulcer itself, is very doubtful.

In the writer's two cases of recovery after perforation, all the symptoms of the ulcer disappeared. In Case I (perforated gastric ulcer) there was no return of the symptoms one year later. In Case IV (perforated duodenal ulcer) there were no clinical evidences of persisting ulceration six months after his discharge from the hospital. In both the entire ulcer had been inverted into the lumen of the viscus. It is likely that the inversion of the ulcerated area leads to necrosis and casting off of the diseased part, and so to spontaneous cure.

However this may be, it does not seem wise to perform gastroenterostomy at the time of perforation, unless there are other indications for it. The patients are usually in a precarious condition, and do not bear well the additional ten to fifteen minutes it would take to perform the anastomosis. The inversion of the ulcer is simple enough. A double row of Lembert mattress sutures, of silk or catgut, passed through healthy tissues at the margin of the ulcer, accomplishes the object. The site of suture should always be covered by omentum or a strip of Cargile membrane, and then protected by a narrow wick of gauze. The omental or membrane covering adds to the security of the suture and prevents a secondary infection of the suture line through the drainage opening.

Where extensive infiltration and brittleness of the tissues surrounding the ulcer causes the sutures to tear out, and so renders closure of the perforation impossible, we may attach the ulcerated area to the anterior parieties, or tampon the perforation with gauze; in either case establishing a jejunostomy by which to administer nourishment.

As to the Peritonitis: The peritoneal surfaces and cavity are carefully cleansed of all extravasated material and exudate by gentle mopping with soft sea sponges or sterile gauze. Evisceration and irrigation of the peritoneal cavity with saline solution is not done; though it is certainly the most efficient method of cleansing the parts, it is too deeply shocking to admit of its employment as a routine procedure.

It is the writer's practice not to drain the peritoneal cavity; such drainage does little good, and disposes to secondary infection, kinking of the intestines and, by irritating the tissues, to a further spread of the infectious material. It has been demonstrated that physically unaltered peritoneum is well able, by its rapid absorptive power, to cope with infectious material, provided it is not injured by chemicals, gauze, or drainage tubes. But wherever the inflammatory process has deprived the peritoneum of its endothelial covering, and has thus retarded the rapidity of its absorptive power; there drainage must be provided, otherwise the products of exudation and bacterial life stagnate at these areas, favoring the spread of the peritonitis. The indications for drainage are not the character of the exudate, but the aspect of the peritoneum. When its endothelial covering is intact and smooth, no drainage is provided; but when the membrane is dull and blistered and converted into granulation tissue it must be thoroughly drained. In the diffuse peritonitis following appendicitis, the writer has obtained the best results by following the above procedure. A series of fourteen cases so treated will be reported in a subsequent communication.

(*b*) *Ruptured Ulcers on the Posterior Gastric Wall.*—Their closure is far more difficult than in the previous instance because of their inaccessibility. The exudate in the retrogastric space is, first of all,

removed by aspiration through the gastrohepatic omentum. The position of the ulcer is then determined by introducing the finger into the retrogastric space through the foramen of Winslow. If it is near the lesser curvature, access to it will best be gained through the gastrohepatic omentum; if it is near the greater curvature, it will be more easily reached from below through the transverse mesocolon. During the manipulations the general peritoneal cavity is protected by gauze compresses. When possible, the ulcer is inverted by Lembert mattress sutures. Drainage of the retrogastric space is provided through a counter incision in the back. Where it is impossible to close the rupture the opening is packed by gauze lead out to the surface through a stab wound in the back, and a jejunostomy established to feed the patient, thus excluding the stomach.

Ruptured Ulcers on Posterior Surface of the Duodenum.—It is to be noted that the posterior duodenal surface is uncovered in the adult by peritoneum. In view of this, it is almost useless to attempt repair of the ruptured ulcer *per se.* The sutures will either not hold in the necrotic cellular tissues, or through secondary infection will give away; in any event, duodenal fistula results, which is apt to end in the speedy death of the patient from starvation. To avoid this, the writer begs to suggest the following procedure:

When the diagnosis is made before operation, it is advisable to evacuate and drain the extravasated material and purulent exudate in the retroduodenal, retrocolic and perinephritic spaces, through a lumbar incision, thereby avoiding any soiling of the peritoneal cavity. The orifice of the ruptured ulcer is tamponed with gauze. The abdomen is then opened, a gastrojejunostomy established, and the pylorus constricted with a purse-string silk suture. The perforated duodenum is thus unilaterally excluded from the intestinal circuit, and leakage of the chyme through the fistula prevented. The procedure is better than a jejunostomy, for gastric digestion is not done away with by it. The duodenal rupture must necessarily close spontaneously by granulation, as there is nothing to leak out and keep it open.

The writer intended performing this operation in his Case III of ruptured ulcer on the posterior duodenal wall, but her wretched condition forbade any secondary operation. It is essential that the gastrojejunostomy and pyloric constriction be done at the time of the first operation, for a duodenal fistula so rapidly exhausts the strength of the patients that they can never be brought into condition to stand a second operation.

In those cases in which the diagnosis is not made until the abdomen is opened, the exudate is evacuated by incising the peritoneum on the outer side of the colon, and drainage established through a small incision in the back. Gastroenterostomy and pyloric constriction are then at once performed.

The writer is led to suggest this procedure of primary gastrojejunostomy and pyloric constriction, *i. e.* unilateral exclusion of the duodenum, because a duodenal fistula is sure to cause speedy death by starvation. As the repair of ulcers on the posterior duodenal wall is most likely to prove unsuccessful, a duodenal fistula will be established and a fatal result is to be expected unless the chyme is diverted from the duodenum. In duodenal fistula due to other causes the same procedure would prove of value.

The patients whose histories follow, one of perforated gastric ulcer on the anterior wall, near the cardia; one of perforated carcinoma on the base of an old ulcer on the lesser curvature; one of perforation of duodenal ulcer on the posterior wall, and one of perforation of duodenal ulcer on anterior wall were admitted to the service of Dr. Gerster at Mount Sinai Hospital, and operated upon by the writer.

Case I (1902, Vol. 2, page 12).—*Perforated Ulcer of Stomach; Diffuse Septic Peritonitis; Laparatomy; Inversion of Ruptured Ulcer by Suture; Drainage of Site of Ulcer; No Drainage of Peritoneal Cavity; Cured.*—Rifka L., eighteen years old, a tailoress, had suffered for the last five years with gastric ulceration; never had hæmatemesis, or melæna. She had been under medical treatment during this time. Three days before admission there was an exacerbation of the symptoms. Thirty-six hours before admission she experienced severe crampy pains in the abdomen, radiating to the left shoulder, and felt faint. She did not vomit; no chill or fever. On admission, October 24, she was in fair general condition. She looked very sick; temperature was 103.8°; pulse, 120. Physical examination revealed heart and lungs normal; abdomen rigid, motionless, with respiration; liver dulness partly obscured by tympanitic resonance. Marked pain and tenderness over entire epigastrium and left hypochondrium, also in right iliac fossa. Rectal and vaginal examination negative.

Diagnosis.—Diffuse peritonitis, from ruptured gastric ulcer.

Immediate Operation.—Under chloroform anæsthesia an indefinite tumefaction was to be felt in the epigastrium. Median laparotomy above umbilicus; the deeper tissues of the abdominal wall were œdematous. On opening peritoneal cavity free, clear fluid escaped from below the level of the transverse colon. Above the transverse colon there was free gas, and thin, greenish-white purulent fluid. Careful protection of the lower half of the peritoneal cavity with gauze compresses. The gas containing, purulent cavity was limited to the right by the triangular ligament of the liver, below by the transverse colon, and extended well over into the left hypochondrium and subphrenic spaces. On lifting up the left lobe of the liver, gas and greenish fluid were seen emerging from a perforation in the anterior wall of the stomach at its cardiac end. The perforation was size of a pea and was imperfectly closed by a gangrenous plug. The edges were sharp and infiltrated and covered with fibrin. The entire ulcer was inverted by three rows of mattress, Lembert sutures of silk, the last row being continuous. Careful cleansing of the infected portion of the peritoneum, and of the left subphrenic region. Protection of the suture line by gauze wick. Closure of rest of wound with through-and-through sutures.

Patient bore the operation nicely; just prior to it she had received an intravenous saline infusion. The convalescence was interrupted by a collection of serous fluid in the left subphrenic space; this caused an elevation of temperature between 103°-104° until it was evacuated through the drainage opening.

December 23, wound all healed; no symptoms of gastric ulcer; eats everything; gained considerably in weight; discharged cured.

One year later: Has not suffered with any gastric disturbance since operation.

Case II (1902, Vol. 2, Page 13).—*Carcinoma of Stomach on Base of Old Ulcer; Perforation; Diffuse Peritonitis; Laparotomy; Closure of Perforation by Covering It with the Omentum; Death on Sixth Day from Sepsis.*—Jennie H., forty-two years old,

a housewife, had suffered with gastric ulcer for seven years. For the three weeks prior to her admission, there was an exacerbation of the symptoms. Frequent vomiting, increased pain, on one occasion vomited two drachms of bright red blood. Lost twelve pounds in weight. On admission November 18, 1902, she was fairly nourished; heart and lungs normal; liver normal, slightly enlarged downward. Abdominal wall lax. In the epigastrium some tenderness, and indefinite mass, which was smooth and flat in outline. From November 19 to 24, she was on the medical service of Dr. Alfred Meyer. During this time she was fed per rectum; vomited blood once. She was apparently doing well until November 24, and had not vomited in forty-eight hours.

November 24, at 10 A.M., she had a very severe attack of pain in epigastrium, accompanied by nausea, no vomiting. The pain was increased by respiration. The abdominal wall was rigid; liver dulness normal. At 1 P.M., abdomen distended and tender and rigid; pain in epigastrium still present. Liver dulness partially obscured by tympany. Dull note in both flanks, shifting with position; temperature 99-101°; pulse rate, 120. Leucocytes, 13,000.

Diagnosis.—Ruptured ulcer of stomach; consent for operation was withheld until 1 A.M. of following day. At that time, fourteen hours after perforation, there were all the evidences of diffuse peritonitis; pulse 140, temperature 101-102°. Leucocytes, 23,000; under gas and ether anæsthesia, I opened the abdomen in the median line from the ensiform downward for five inches; escape of free greenish fluid and some gas on incising the peritoneum. On the lesser curvature, covered over by the left lobe of the liver was a perforation of the stomach, imperfectly closed by a layer of necrotic fibrin. The perforation was in the center of a dense area of infiltration, that measured about 2½ inches in diameter, and about 1 inch in thickness. The perforation was in an inaccessible position, laying behind the gastrohepatic omentum. Closure of the perforation by Lembert sutures was unsuccessful, for the sutures would not hold in the infiltrated tissues. The area of infiltration was too wide to permit of inverting it into the lumen of the stomach. Resection was impossible on account of the wretched condition of the patient. The omentum was therefore reflected upward over the stomach and sutured all around the edges of the perforation, and to the infiltrated area. Protection of suture line by gauze wick; cleansing of the peritoneal cavity; closure of the rest of the abdominal wound. The patient's pulse at end of operation was 170-180; temperature rose to 103.6°. Vigorous stimulation caused but a poor reaction. The next day the pulse declined to 130-140; temperature 100-103.6°. The following day patient had a severe chill, and temperature rose to 105°; pulse 118-140. Urine acid, 1014, trace of albumin and casts. The gauze wick was renewed on the fourth day. There was no leakage. Water and barley-water were given by mouth; temperature between 103-104°. Leakage through the drainage opening occurred on the fifth day; pulse poor, 140; temperature, 104°. On the sixth day the patient failed rapidly and died. Autopsy through wound—no peritonitis. Large area of dense infiltration 2½ inches in diameter on anterior surface and lesser curvature of stomach—in its center, and about 5 c.m. from pylorus, a perforation, covered over by omentum which is adherent to the edges of the opening, but permitted slight leakage at either side; two healed ulcers near pylorus—pylorus not stenosed. Liver normal; no gallstones; spleen soft and white; mesenteric nodes enlarged; microscopic examination of infiltrated area, adenocarcinoma on basis of old ulcer.

CASE III (1901, Vol. II, page 84).—*Ulcer on Posterior Wall of Duodenum; Perforation into Retroduodenal Space; Retroduodenal Abscess Burrowing Downward Behind Ascending Colon; Incision and Drainage; Duodenal Fistulæ; Death from Inanition Nine Days after Operation.*—Tillie B., eighteen years of age, had an attack of catarrhal appendicitis (?) several months before her present illness; this was not accompanied with fever or vomiting. Otherwise she was always perfectly well until ten days before I saw her with her attending physician, Dr. Wurthman. At that time she was taken with fever, pain in the right iliac fossa and vomiting. Pain and fever continued ever since; vomiting ceased after two days; no chills.

On admission, September 13, 1901, physical examination revealed normal internal organs. In the right side of the abdomen, behind the ascending colon, was a large, smooth very sensitive tumefaction. Liver and splenic dulness unchanged. *Urine* acid, 1019, trace of albumin; few hyaline and granular casts; temperature 101.4°.

Diagnosis.—Retrocolic abscess, probably due to perforative appendicitis. Laparotomy on same day; Sonnenberg incision over abscess mass; abdominal wall œdematous. On incising peritoneum there was a profuse discharge of stinking pus from a large abscess cavity behind and to outer side of upper part of ascending colon. Appendix not sought for; tube and gauze drainage. During the operation the pulse rate rose to 150–160 to the minute and was of very poor quality. Patient cyanotic and respiration much impaired. The patient's poor condition forbade any exploration of abscess cavity.

September 14.—General condition of the patient was much improved. There was a profuse acrid, watery discharge, of acid reaction, from the wound, necessitating repeated change of superficial dressings.

September 15.—The deep dressings were changed on the 15th. A very acid, brownish, watery material with some fecal matter was discharged from the abscess cavity behind the ascending colon. It contained no evidences of milk, which the patient took by mouth. The edges of the abdominal incision were reddened and eczematous. The fecal matter in the discharge indicated a communication of the colon with the abscess cavity. The brownish acid watery material, though containing no evidences of milk, which the patient took by mouth, was thought to come from the duodenum, into which the abscess had possibly perforated. The patient's wretched condition forbade any further operative interference. The intestinal fistula was plugged with gauze, but the continued leakage could not be stopped. On September 16 a gangrenous piece of tissue, resembling in size and shape the appendix, came away in the discharge from the wound. Gradual failure of pulse, inanition, death on September 21, 1901. Highest temperature, 101.8°.

Autopsy—through the Wound.—Large cavity behind the ascending colon through the abdominal incision. Into this cavity opened three perforations in the posterior wall of the ascending colon, through which the fecal matter had discharged. (One of these openings was 2 cm. in diameter.) The upper part of the abscess cavity communicated through a perforation on the posterior wall of the duodenum with the interior of this viscus. This opening was

8 cm. from the pylorus, was 1.5 cm. in diameter, and had necrotic edges.

Kidneys.—Congestion and degeneration; right kidney surrounded by adhesions. Microscopical Examination: Congestion; slight increase of connective tissue.

Spleen.—Small; increase of connective tissue.

Liver.—Congested; fatty.

Stomach.—Acute inflammation of mucosa, with hemorrhages.

Case IV (1902, Vol. 2, Page 25).—*Perforation of Ulcer on Anterior Wall of Duodenum; Diffuse Purulent Peritonitis; Laparotomy; Inversion of Ulcer by Suture; Cleansing of Peritoneal Cavity; Protection of Site of Suture by Wick of Gauze; No Drainage of Peritoneal Cavity; Cured.*—Samuel T., twenty-one years old, a clerk, had been well until six days before his admission, when he was nauseated and vomited. Twenty-four hours before admission he suffered sudden severe stabbing pain, in the right iliac region, and vomited shortly afterward. Had chilly sensations; urination normal.

On admission, August 13, he was in well nourished state; flushed face, dry tongue; temperature 101°, pulse 108; lungs, heart normal. Liver and spleen normal; no obliteration of normal dulness.

Abdomen.—Rigid; marked point of tenderness over superior iliac spine. Dulness in both flanks shifting with change of position.

Diagnosis.—Acute gangrenous appendicitis with peritonitis.

Immediate Laparotomy; abdomen opened by Kammerer's incision in right iliac fossa. On incising the peritoneum, there was an escape of free gas and purulent non-odorous fluid. Intestines distended and highly injected. Appendix normal, except that its peritoneal coat was injected. Patches of fibrin and collection of non-odorous purulent fluid were scattered all over the small intestines. No perforation was found in the small or large intestines. The incision was prolonged upward to the freed border of the ribs, to expose the stomach and duodenum, liver and gall-bladder. There was a considerable fibrinous exudate covering the pyloric portion of the stomach, and first and second portions of the duodenum. Beneath this fibrinous deposit on the anterior aspect of the descending duodenum was a perforation about ½ inch in diameter, from which escaped bile and thin fluid material. The perforation was not completely closed by the plastic exudate, and intestinal contents were being constantly discharged into the peritoneal cavity. The ulcer was inverted by a longitudinal infolding of the anterior duodenal wall, with two layers of Lembert silk sutures. Suture line covered by omentum; protection of suture line by narrow gauze wick; careful cleansing of peritoneal cavity. No drainage; closure of abdominal wound except at extreme upper angle where the narrow gauze wick emerged.

The patient reacted well from operation; highest temperature (102°) was on following day; highest pulse rate 128. Nothing allowed by mouth; rectal alimentation and stimulation; vomited repeatedly dark green material for forty-eight hours; bowels moved by enemata on the third day. Water and beef juice given by mouth on the fourth day. Wound healed primarily. No leakage from duodenum; uneventful convalescence. Discharged cured September 14, 1903. Six months later patient was in excellent condition. Had excellent appetite; suffered no pain after eating.

RESULTS OF PREVENTIVE MEDICINE IN PROVIDENCE, R. I., 1885–1902.

By FREDERICK S. CRUM,

NEWARK, N. J.

It is an unquestionable fact that the crude mortality rate in our American city population has declined noticeably in recent years. It is generally conceded that this satisfactory result has been brought about by improvements in sanitary science, practically applied by municipal authorities, and by progress in medical science, made possible by modern pathological researches. Due credit should be given both to health organizations and the medical profession for the almost marvelous results which are being wrought, silently but effectively, in the warfare of science with disease.

I wish here to direct attention to a few specific facts relative to improved mortality in Providence, R. I. The excellent results to which the following facts bear witness are doubtless to be accredited, in large part at least, to the efficient labors of the Superintendent of Health and the City Registrar, Charles V. Chapin, M.D. His annual reports in his two official capacities are models of their kind, and the figures here presented have been compiled from the report for 1902 as Superintendent of Health of the City of Providence.

The physicians of Providence are required to report the cases of certain communicable diseases which come to their notice, and these data, with the number of deaths from the same diseases, make possible the calculation of the ratio of fatalities to cases reported. Such records are available for Providence for a period of eighteen years for typhoid fever, diphtheria, scarlet fever, and smallpox. Of the last-mentioned disease there have been but seventy-two cases and thirteen deaths in eighteen years, and smallpox may therefore be dismissed from the present discussion as being relatively unimportant as a cause of sickness or death in Providence.

In the eighteen years (1885–1902) under observation there have been 3,090 cases of typhoid fever reported in Providence, and the following table is significant:

MORTALITY FROM TYPHOID FEVER, PROVIDENCE, R. I., 1885–1902.

Years.	Cases.	Deaths.	Per cent. of Cases Resulting Fatally.	Rates per 10,000 Population. Case Rate.	Death Rate.
1885–1890	951	337	35.4 per cent.	12.6	4.5
1891–1896.....	1,178	319	27.1 "	13.8	3.8
1897–1902.....	961	229	23.8 "	9.3	2.9
1885–1902	3,090	885	28.6 per cent.	11.7	3.4

It is shown by the above table that the ratio of deaths to cases has declined from 35.4 in the first six-year period to 23.8 in the last six-year period. Here appears to be evidence that medical treatment has had more to do with the improved mortality than sanitary science. The number of cases of typhoid fever reported was larger per 10,000 of population in 1891–96 than in 1885–90, but the ratio of deaths to cases was so much less in the period 1891–96 that the typhoid fever death-rate was only 3.8 per 10,000 of population in 1891–96 as against 4.5 in the period 1885–90. In the last six-year period sanitary improvements and medical science have apparently both operated effectively, the one to reduce the number of cases; and the other to reduce still further the ratio of deaths to cases.

In the period 1885-1902 there were 6,213 cases of diphtheria brought to the attention of the Provi-

dence Health Department. The following table succinctly states the essential facts:

MORTALITY FROM DIPHTHERIA, PROVIDENCE, R. I., 1885–1902.

Years.	Cases.	Deaths.	Per cent. of Cases Resulting Fatally.	Rates per 10,000 Population. Case Rate.	Death Rate.
1885–1890.....	1,618	532	32.9 per cent.	21.6	7.1
1891–1896.....	1,987	383	19.3 "	23.3	4.5
1897–1902.....	2,608	313	12.0 "	25.2	3.0
1885–1902	6,213	1,228	19.8 per cent.	23.6	4.7

The figures presented in the above table are especially striking. It is shown that the ratio of deaths to cases has steadily declined, the average for the first period being 32.9 per cent. and for the last period 12.0 per cent. On the other hand, diphtheria cases have increased, both in actual numbers and relatively to the population. So great has been the improvement in the medical treatment of this disease, however, that the death rate has declined from 7.1 per 10,000 of population in 1885-1890 to 3.0, or less than one-half, in 1897-1902. It is probable that cases of diphtheria are diagnosed with more certainty now than formerly, and that this fact, together with greater vigilance on the part of health officials, may account in part for the increase in the number of cases reported. On the other hand, many suspicious cases which formerly would have passed for diphtheria are now, under the improved methods of diagnosis, dismissed from this category. It is not my purpose here to discuss the efficacy of antitoxin as a method of warfare against this particular disease. I may, however, venture the suggestion that the improvement in mortality under this head may be largely due to the undoubted fact that diphtheria cases are more quickly taken in hand now than was formerly true, and early treatment of this disease is especially important if the best results are to be effected.

During the period 1885-1902 there were 8,343 cases of scarlet fever brought to the notice of the Providence Health Department, 700 of which terminated fatally. The following table sets forth the facts:

MORTALITY FROM SCARLET FEVER, PROVIDENCE, R. I., 1885–1902.

Years.	Cases.	Deaths.	Per cent. of Cases Resulting Fatally.	Rates per 10,000 Population. Case Rate.	Death Rate.
1885–1890.....	2,127	333	15.7 per cent.	28.4	4.4
1891–1896.....	4,070	304	7.5 "	47.8	3.6
1897–1902.....	2,146	63	2.9 "	20.7	0.6
1885–1902.....	8,343	700	8.4 per cent.	31.6	2.7

The ratio of deaths to cases reported shows an even more noticeable decline in the statistics of scarlet fever than in typhoid fever and diphtheria. From 15.7 deaths in every 100 cases to 2.9, is, indeed, a noteworthy result. Fatalities among scarlet-fever patients were less than one-fifth as frequent in 1897-1902 as in 1885-1890. In the period 1891-1896 there were nearly as many cases reported as in the two other periods combined, but, in consequence of the reduced ratio of deaths to cases, the actual number of deaths was less in that period than in 1885-1890. The scarlet-fever death rate per 10,000 of population has fallen from 4.4 in the first period to 0.6 in the last.

In all three of the diseases here considered, it appears that the death rates have steadily fallen in the last eighteen years when we consider the period as divided into three equal parts. Of the three causes of death the mortality from diphtheria has been uniformly highest. The mortality from typhoid and scarlet fever has been approximately the same in the first two six-year periods, and much less from scarlet fever in the last period.

The ratio of deaths to cases has been uniformly highest for typhoid fever and lowest for scarlet fever. A noteworthy reduction has taken place in these ratios for all three diseases, a reduction out of all proportion to the reduction in the number of cases reported, these having, in fact, increased in some instances, both in actual numbers and relatively to the population. This would seem strongly to point to the conclusion that improved methods of diagnosis and more skilful medical treatment have played a large part in bringing about the gratifying results indicated in the tables here presented.

FATAL GASTRIC HEMORRHAGE WITH AUTOPSY.

By MARSHALL LANGTON PRICE, M.D.,

BALTIMORE, MD.

MEDICAL OFFICER STATE TUBERCULOSIS COMMISSION OF MARYLAND LATE ASSISTANT RESIDENT PHYSICIAN, UNIVERSITY HOSPITAL, BALTIMORE.

In the case of fatal hemorrhage into the stomach, which is here described, we have to consider some features of considerable interest, not alone from the fact that death from gastric hemorrhage is itself rather rare, but also from the fact that it brings up, in a striking manner, the whole subject of internal hemorrhage, which has always possessed a fascination out of proportion to its frequency. The reason for this is easy to understand when we consider its usually sudden and unexpected appearance, and the terrible rapidity with which it destroys life before we are even aware that our patient's vital forces have been threatened by so ominous an enemy.

There is perhaps no other condition in medicine in which every moment is full of such golden opportunity for timely aid, or in which the result of delay is such extensive devastation. Probably in the majority of cases of wholly concealed hemorrhage, if we except postpartum hemorrhage, before we awaken to the danger the patient's life has ebbed with the receding tide of blood and he is beyond the reach of all our endeavors.

Probably the most frequent of these concealed hemorrhages are those occurring in connection with childbirth and the puerperal period; but this form of hemorrhage, by its very frequency, furnishes a safe-guard. The obstetrician, aware of this danger, is ready to recognize it and to combat it should it occur; yet death has occurred from this cause unsuspected, and in the hands of the most able obstetricians.

It is in these cases that the necessity for close and careful observation is emphasized—of the clinical features of every case. The difficulties of diagnosis in such cases may best be appreciated by citing a case such as the one here described: A man in failing health, with pallor, weakness, and shortness of breath on exertion, with local symptoms slight or absent, has either a sudden exacerbation of these symptoms or a more or less gradual aggravation of them; the pulse fails, the patient sinks and dies. The case comes to autopsy and the physician is astonished to find that one of the hollow viscera is filled with blood, and only then recognizes the significance of the previous symptoms.

The symptoms of hemorrhage are too well known to require repetition. There is no one symptom—unfortunately—pathognomonic of hemorrhage, yet the train of symptoms, if carefully noted, is sufficiently characteristic to justify a diagnosis. Generally speaking, it is well for the physician to watch carefully cases of inexplicable prostration which show the three cardinal symptoms of anxiety, restlessness, and thirst.

The diagnosis of hemorrhage, without the external appearance of blood, is always a matter of great difficulty. The diagnosis previous to death, in this

case, constitutes one of its most interesting features.

I. W. C., married, aged fifty years, entered the medical ward of the University Hospital a little after noon, June 30. He was able to walk fairly well with the support of two colored boys, who had brought him to the hospital, supporting him on either side. His pallor and exhaustion were noticed, and he was put to bed at once and given his bath in bed, instead of being sent to the tub as was customary with ambulatory patients.

Immediately after the bath, I proceeded to make the usual physical examination, assisted Mr. Gentry, to whom the note was dictated.

The probationer nurse took his temperature, which was 95° F. The following is the note dictated to the clinical assistant:

Physical Examination.—Patient is a rather heavily built man. Height, five feet six inches. Muscles very flabby, subcutaneous fat well preserved, skin has a blanched hue, with a faintly yellowish tinge. Expression apathetic, eyes sunken, conjunctivæ clear, with a pearly luster; pupils react readily to light and accommodation and are of equal size. Superficial capillaries of both cheeks, and both alæ nasi dilated. Patient very listless and drowsy. The skin all over the body is pale and cold. Extremities cold; finger tips slightly clubbed, and nails somewhat incurved; tongue pale and coated with a whitish fur; teeth very bad; slight pulsations of the vessels of the neck.

Chest.—Well developed. Supra- and infraclavicular spaces on the right side slightly sunken; right shoulder a trifle lower than the left; right thorax somewhat deficient in size; expansion good, little deeper on the left side; both right supra- and infraclavicular spaces give a slightly diminished percussion resonance, with slightly elevated pitch; apex of right lung reaches clavicular level; apex of left lung rises somewhat above the clavicle; costal angle about 45°; respirations are slow and slightly irregular.

Breath sounds roughened over right apex; slight friction murmur; a few low-pitched sonorous râles are heard, accompanied by a prolonged expiratory murmur; the skin over the front of the chest appears somewhat œdematous. . . . Respiration is of the Cheyne-Stokes' type. . . .

Heart.—Impulse feeble and diffuse, most marked in fifth interspace, about 4 cm. within the left mammillary line. The P. M. C. I. lies in the mammillary line; cardiac impulse fairly forcible at the apex, and is accompanied by a soft systolic murmur; second aortic and pulmonic sounds very distant and feeble.

The patient during the course of the examination, roused from his apathy, and became very restless. He now appeared to be in great distress and struggled to a sitting posture in a severe dyspnœic seizure. He appeared at once evidently desperately ill. The marked pallor noted on entrance had deepened to an extreme lividity; the eyes became sunken, the features pinched, the skin cold and covered by a profuse sweat. The pupils dilated widely and became irresponsive to light; the expression showed great anxiety, and he complained of smothering; thirst was intense and he swallowed water eagerly. Owing to the Cheyne-Stokes' respiration, which still persisted, his dyspnœa was ascribed to renal asthma, and he was given morph. sulph. ¼ gr., with little relief, and whiskey and strychnine by mouth. While these were being given, the patient had an involuntary evacuation of the bowels, and on turning aside the bedclothing, about two ounces of black tarry matter could be seen, and on close examination a reddish stain noted on the linen.

This latter occurrence seemed to offer a rational explanation of the previous symptoms, and a diagnosis was made of internal hemorrhage, probably gastric, and measures were immediately taken to combat it.

The patient still remained restless, but his progressive weakness prevented him from rising. The patient's right breast was hurriedly prepared by Mr. Gentry, the long needle introduced, and 400 c.c. of hot normal saline solution injected. Miss Dilworth, the junior nurse, was directed to take the patient's pulse. She stated that it became perceptible at the wrist after the infusion. All of the solution introduced was readily absorbed. He was now given 700 c.c. additional, which was also rapidly absorbed. The foot of the bed was elevated, the patient covered with blankets, and surrounded with hot water bottles. A drachm of ether was given hypodermically.

The pulse still failing, preparations were made to transfuse directly into a vein. The median basilic was dissected out, ligated, and the needle introduced. About 400 c.c. further were allowed to flow into the vein. This latter was not taken up, as the circulation had almost wholly failed. The patient was now seen to be *in extremis* and the needle was at once withdrawn, the vein ligated, and the arm hurriedly dressed and bandaged. The pulse was gone in the carotids, and the heart beat imperceptible; the lower jaw had fallen.

Respiration persisted for about a minute, consisting of few inspiratory gasps, at intervals of about twenty seconds.

Autopsy, by José Hirsh, M.D. Died at half-past three. Autopsy at 4.15 P.M., three-quarters of an hour after death.

Rigor mortis not present. Body length, 165 cm. Well-built man, quite muscular, abdomen soft, not distended. Pupils dilated; diameter 7 mm. Teeth badly formed; incisors of the upper maxilla missing; no post-mortem lividity.

On the posterior surface of the thigh are two abrasions, and on the anterior surface of the right arm above the elbow is a small opening in the skin, which is the seat of a transfusion. No scars or lesions about the body. No scars about prepuce. A large amount of subcutaneous fat is present.

Peritoneal cavity dry. Peritoneum smooth and glistening.

Tissues.—Muscles on the chest very moist and œdematous, especially on the right side about the pectoral muscle, where the patient has been transfused.

Abdominal cavity, on inspection appears normal Omentum well infiltrated with fat.

Intestines.—Normal in appearance not distended. At the ileum, cæcum, and sigmoid flexure are seen moderate-sized sacculations, the contents of which appear dark through the intestinal wall, and on section they are found to be distended with partially clotted blood; the three sacculations probably containing from three to four pints.

On opening the chest, the lungs are found perfectly free, not adherent anywhere. No fluid is to be found in the pleural cavity.

Appendix is seen lying on the under surface of the cæcum, extending downward toward the pelvis; length, 10 cm.

Pericardium contains a small amount of yellowish fluid. Fat in the mediastinum is œdematous, and contains a small quantity of air.

Heart.—Apex of the heart at the fifth intercostal space slightly within the mammillary line. The

anterior surface is covered by a rather large amount of fat. The heart is slightly enlarged; weight 390 gms. The right auricle is smooth; tricuspid valve, normal. Right ventricle, 6 mm. in thickness. Left auricle, smooth. Mitral valve presents numerous thickenings along the edges and feels hard and dense. Thickness of the left ventricle 2 cm. The coronary arteries are rather sclerotic.

Left lung rather shrunken. No nodular masses to be felt. Crepitates freely. At the root of the lung are seen small, hard, black bronchial glands. One section has a gray mottled appearance, showing no areas of inflammation, bronchi nowise conjested. The lung is rather dry, and does not readily exude fluid on pressure. The right lung does not show marked division of its lobes, the middle lobe being rather small. Mottled appearance, crepitates freely, some pigmentary deposits about bronchial glands. On section the same appearance is seen as in the left lung.

Stomach is markedly distended and shows a dark appearance through its walls, and on section fluid and partly clotted blood exudes to the amount of about two gallons. The weight of the whole being estimated at about ten pounds. Near the cardiac end on the posterior-surface there is a large sloughing mass, about 8 cm. long, 5 cm. wide. The entire mucosa in the neighborhood has sloughed away from this space. Numerous foul-smelling granulations arise. The ulcer has entirely perforated through the stomach and is firmly adherent to the left lobe of the liver. This adhesion is very firm and can only be separated by considerable force. The stomach about this area is congested, but shows no other areas of ulceration.

On the outer surface of the stomach where adherent to the liver there is present an ulcerated area about 4 by 3 cm., tissue soft and necrotic.

The base of the ulcer contains a mass of cauliflower granulations, which are soft and easily broken down. The ulcer begins about 1 cm. from the œsophageal opening, but does not involve the œsophagus.

The opening of the gall duct into the duodenum contains a small amount of bile, but no stones.

Liver is normal; weight, 1,800 grams On section somewhat glazed, not congested, under surface of right lobe has a small nodule, which on section is perfectly white, umbilicated at the center, and contains a small amount of exudate and fluid.

The m.m. of the gall-bladder is deeply bile-stained, and presents a smooth surface—no stones.

Spleen 12 by 6 by 2 cm.; weight, 175 gm. On section somewhat thickened and the malpighian bodies stand out more or less prominently.

Left kidney.—Slightly enlarged; weight, 170 gm.; surface rough, easily stripped off capsule. Substance of the kidney pale; cortex slightly contracted. Malpighian bodies stand out more or less prominently.

Right kidney.—Slightly larger; weight, 180 gm.; surface rough, capsule easily stripped off. Substance of the kidney pale; cortex slightly contracted. Malpighian bodies normal; size 8 by 5 by 2 cm. It presents on its surface small cysts, containing a rather dirty-brown fluid. Substance mottled and slightly hemorrhagic. Cortex somewhat congested. Malpighian bodies well marked, size 10 by 5 by 2½ cm. Capsule easily stripped off.

Bladder.—Somewhat thickened, otherwise normal.

Brain.—Vessels not congested, surface rather dry, and covered by a semigelatinous mass. Vessels not atheromatous. Ventricles do not contain much fluid and are not enlarged.

Aorta perfectly smooth and normal.

In addition to confirming the clinical diagnosis of death from gastric hemorrhage, the autopsy showed several other interesting features. The ulcer, on sectioning and microscopic examination, proved to be due to a colloid carcinoma. The fact of the ulcer having penetrated the stomach wall and having invaded a considerable part of the substance of the left lobe of the liver, without exciting any evidence of a peritonitis, either local or general, is one that has been frequently observed in colloid carcinoma. In one case coming under Osler's observation, the ulceration had destroyed a large part of the pyloric end of the stomach, and nearly the whole of the left lobe of the liver lay within the gastric cavity.

The small cyst noted on the inferior portion of the liver was due to the echinococcus.

A meager history was obtained from the man's wife after death. She absolutely denied his ever having vomited blood or dark fluid, or, in fact, having vomited at all. She denied the passage of blood by the bowels. He had been under the treatment of a physician for several weeks for "nervous gastritis," and not improving he was sent to the hospital. His wife was much incensed by his death occurring so soon after entering the hospital. It is probable from the man's appearance that he had been losing blood in small quantities for some time, and that a sudden and overwhelming hemorrhage had occurred synchronously with his entrance into the hospital.

The remarkable tolerance of both the bowel and stomach to the blood which they contained, can only be explained by the patient's fatal prostration before vomiting could occur.

The promptness of treatment in this case must necessarily have served to prolong life, though the large amount of saline solution thrown into the circulation (about two quarts) only formed a small portion of the blood in the stomach alone. If the blood had been extruded more slowly, and the stomach made an attempt to contract on its contents, it seems possible that life could have been prolonged until a thrombus could form in the eroded vessel, and a fatal issue averted. The loss of blood in gastric ulcer is sometimes enormous, but death only rarely follows. A more common cause of fatal hemorrhage is that from the dilated oœsphageal varices in cirrhosis of the liver. Fatal hemorrhage from colloid carcinoma or other malignant affections of the stomach must be considered as extremely rare. VanValzah says, "Bleeding from carcinoma is rarely profuse . . . erosion of an artery may occur . . . causing fatal hemorrhage." He cites no case in which this occurred. Hemmeter, Cruveilhier, Budd, Finny, Powell, and Welch cite cases of death from gastric hemorrhage due to ulcer, but mention no cases due to carcinoma, though several of them mention such a possibility. Bouveret cites the only case found after a fairly extensive search of the literature on the subject. The following is a short translation . . . "the vomited matters in carcinoma contain blood constantly, but it is rare that the amount is abundant, and especially rare that it is pure. . . . "A patient with carcinoma of the stomach had a hemorrhage sufficiently profuse to cause collapse." . . . "the second hemorrhage proved fatal" . . . the stomach contained an enormous clot weighing 500 gm. . . . the coronary artery was opened. Bouveret states that severe hemorrhage occurs in 7 to 8 per cent. of all cases of carcinoma gastrica. (Bouveret, "Maladies de l'Estomac.")

The diagnosis of fatal hemorrhage without hæmetemesis seems to have never been made by any of these observers. Cruveilhier and Budd each

report cases, in one of which the stomach and in the other the stomach and intestinal tract were filled with blood. The diagnosis was made by autopsy. In Finny's case the ulcer had penetrated the left ventricle of the heart. Ewald cites a case in which even after several severe attacks of hæmatemesis, in the last of which the patient died, the immediate cause of death was doubtful, owing to some of the very nervous symptoms noted in the present case. He described the patient as . . . fully unconscious, faint conjunctival reflex, small wiry pulse, retracted abdomen, cold skin. . . . Cheyne-Stokes' respiration was present. He suspected the presence of a cerebral appoplexy, but the case proved at autopsy to be simple hemorrhage. Osler cites a case in which a middle-aged woman fell suddenly dead on the floor. At the autopsy about five pounds of blood were found in the stomach.

THE LOCAL TREATMENT OF ACUTE AND CHRONIC GONORRHŒA.

By R. O. KEVIN, M.D.,
PHILADELPHIA.
ATTENDING SURGEON, GENITOURINARY DISPENSARY, JEFFERSON MEDICAL COLLEGE HOSPITAL.

The treatment of gonorrhœic infections by means of urethral injections stands to-day as the most approved principal method at our disposal; the success of this plan of treatment is dependent upon the drugs used for injection, the use of appropriate internal medication in selected cases, and the proper adaptation and variation of the treatment in accordance with the pathological conditions present and the individual requirements of cases.

The experience of genitourinary surgeons in the local treatment of gonorrhœa has led to the now-accepted conclusion that the qualities which a drug used for injection should possess are, non-irritating character and bactericidal strength sufficient to destroy the gonococci on the surface and in the deeper layers of the urethra. As a result of years of experimentation with all the known antiseptics, from bichloride of mercury to boracic acid, silver has been evolved as the most efficient agent for injection into the urethra; the problem has been to obtain silver in such a form that it would be free from irritating properties and possess the ability to reach the gonococci in the deeper tissues.

Silver nitrate, which is indispensable in certain chronic conditions of the urethra, is, because of its irritating properties and its inability to penetrate beyond the surface, ill-adapted to the large majority of cases; consequently the other salts of silver have been tried as substitutes for the nitrate. Some of these newer silver salts have proved of value in the acute cases, but are of limited utility because of the small amount of silver contained (4 to 11 per cent.) and because strong solutions possess, although to a less extent, the irritating properties of the nitrate. It was, therefore, with much interest that I read in the Medical Record, May, 1902, of the discovery of a new silver salt (argyrol or silver vitellin) which contained 30 per cent. of silver and, according to several of the most conservative genitourinary surgeons (Belfield, Swinburne, Christian, Lewis (could be used in strong solutions in an acutely inflamed urethra without producing irritation.

My experience with argyrol began last July in the service of Prof. Orville Horwitz at the genitourinary dispensary of the Jefferson Medical College Hospital, since which time I have observed its effects in at least 2,500 cases of acute and chronic conditions of the genitourinary organs; I have had, therefore, an exceptional opportunity to study the drug clinically, and desire to record my personal observations and conclusions, the value of which consist chiefly of a description of the methods of use which I have found most satisfactory.

Acute Gonorrhœa: Although argyrol is used at the clinic in all cases of acute gonorrhœa where injections are indicated, my personal observations are based upon cases occurring in private practice, as my work at the dispensary consists of the treatment of chronic conditions. The methods I use in treating acute cases vary with circumstances. If a patient presents himself during the first forty-eight hours, I try the abortive method, which is as follows: The anterior urethra is washed with warm water in order to remove the accumulated discharge; an ordinary hand syringe is used for the purpose. Then I inject two drachms of a twenty-per-cent. solution of argyrol into the anterior urethra and hold it there for ten minutes; while making this injection I instruct the patient carefully concerning all the details as to the proper method of doing it. He is then given a twenty-per-cent. solution for use at home and the injection, as described above, is repeated every three hours *night and day* for two or three days; the patient reports at the office once daily for observation. This treatment is a troublesome one and expensive; but the fact that I have seen six cases of severe acute gonorrhœa, so treated, aborted in from four to ten days justifies its employment in every case seen during the first forty-eight hours. Even if, as is usually the case, the disease is not aborted, my experience has proved the wisdom of using this method because of the great comfort it affords the patient and the fact that a cure is effected in a much shorter period; in this connection I use the word "cure" as designating disappearance of the gonococci, cessation of discharge, successful trial of the "beer test" and personal observation of the patient for as long a time as he can be induced to periodically visit the office.

In cases seen after the first forty-eight hours, the plan of treatment is governed largely by the financial condition of the patient. If comfortably situated I prescribe five-per-cent. solution argyrol, two drachms of which are injected into the urethra three or four times daily and retained five to ten minutes. A five-per-cent. solution is used because I believe the stronger solution of any silver salt, the better will be the results, and argyrol is the only one I have been able to use so strong in an acute gonorrhœa without intensifying the symptoms. If the patient is poor, I prescribe a one, two, or three-per-cent. solution according to his means, and have him visit the office every two or three days for an injection of a ten to twenty-per-cent. solution of argyrol; this plan I have found eminently satisfactory and one well adapted to the average run of cases. I do not irrigate acute gonorrhœa. The plan, as above outlined, has enabled me to discharge 85 per cent. of my private acute cases in from three to six weeks; the remaining 15 per cent. constitutes the usual proportion that drift into the chronic conditions which occur in spite of the most varied and energetic measures. One point concerning argyrol which is strikingly noticeable is its very positive influence in allaying the signs and subjective symptoms of inflammation, and the stronger the solutions employed, the more pronounced the effects.

Of chronic affections of urethra and adjacent structures, I see on an average ten to twenty-five cases a day at the clinic in addition to a considerable number in private practice.

Chronic anterior or antero-posterior urethritis is first irrigated with a warm saturated solution of

boracic acid. Every two or three days an applicator wrapped with cotton saturated in twenty-per-cent. argyrol solution is then passed into the urethra and moved gently to and fro, much in the same manner as local applications are made to the nasopharynx. The patient is given a five-per-cent. solution for injection three times daily.

In chronic follicular urethritis and Cowperitis a ten-per-cent. solution of argyrol is injected, preceded in the former condition by dilatation of the urethra.

Seminal vesiculitis is treated by thorough massage through the rectum while the bladder is full; the patient then urinates, after which one-quarter to one-half ounce of ten-per-cent. argyrol solution is injected by means of a Keyes-Ultzman syringe.

Cases of cystitis receive preliminary irrigation with saturated solution of boracic acid; this is followed by injection of one-half to one ounce of ten to twenty-per-cent. argyrol solution into the bladder, which is allowed to remain there.

In the treatment of chronic posterior urethritis I have found the suggestion of Swinburne valuable, *i.e.* that argyrol be incorporated into an ointment with lanoline as a base and passed into the posterior urethra by means of sounds. Swinburne recommends five-per-cent. argyrol, but my experience has been more satisfactory with a twenty-per-cent. ointment, which I apply on cup sounds. In addition to this, the patients are given preliminary irrigations (1 to 1,000), followed by deep instillations of ten-per-cent. solution of argyrol every two or three days.

Belfield of Chicago has reported good results from the use of argyrol in infection of the prostatic follicles in cases of enlarged prostate. I have found that irrigation followed by instillation of twenty-per-cent. solution into the deep urethra and bladder rapidly eliminates the infection of the follicles and affords relief from the symptoms. Infection of the bladder from habitual use of catheters is now less frequently seen than formerly, but when they do occur I inject one ounce of twenty-per-cent. solution into the bladder and allow it to remain there.

Of gonorrhœa in the female I have seen about seventy cases involving the urethra, cervix, and endometrium, all of which I have treated with argyrol either alone or in combination with other drugs. The method of using the drug was practically the same as that employed by Small at the University Hospital, and described by him in the *American Journal of Obstetrics*, January, 1903. My results in these cases are now being embodied in a paper which I have been invited to read at a coming meeting of the Philadelphia Obstetrical Society and which will be published later.

In all of the above mentioned chronic conditions of the urethra and adjacent structures, I have witnessed most decided improvement from the judicious use of argyrol in appropriate strength and at suitable intervals. Where formerly silver nitrate was practically the only drug used, I have been able, in the majority of cases, to replace it advantageously with argyrol and have consequently spared the patients the burning sensation and pain which always accompany the use of the nitrate. Furthermore the results, both in regard to relief of symptoms and therapeutic effect on the pathological conditions, are better than follows the use of the nitrate; I attribute this to the large amount of silver in argyrol, which permits the use of sufficiently strong solution to obtain the effect of the silver without producing irritation.

These chronic conditions constitute a large part of the genitourinary surgeon's work, and many of them tax his skill in diagnosis and treatment to the utmost, and even in the best hands often prove intractable; but it is my conviction that we have never had a single drug that so favorably influences the majority of these chronic conditions as does argyrol, nor one that can be so safely used by the average physician. We have not, however, attained the millennium of invariable success, and the prime factor of successful treatment still remains the careful study of the condition present, adaptation of proper means to the individual cases, and persistence in carrying out the treatment.

1315 South Fifteenth Street.

PRELIMINARY REPORT OF A SUCCESSFUL OPERATION FOR THE RADICAL CURE OF COMPLETE PROLAPSE OF THE RECTUM OF SIXTEEN YEARS' DURATION IN A CASE OF PRIMARY DEMENTIA.

By JOHN RUDOLPH KNAPP, M.D.,
ASSISTANT PHYSICIAN MANHATTAN STATE HOSPITAL, EAST. WARDS ISLAND, NEW YORK.

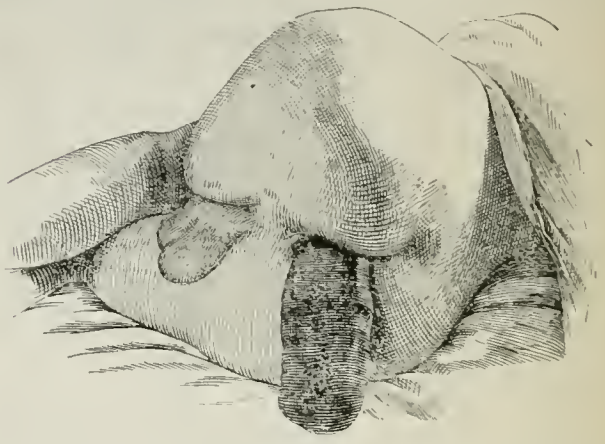
Case J. D., admitted to the Manhattan State Hospital, East, April 3, 1888. Age twenty years. Nativity, United States. Occupation, None. Single.

Duration of insanity, previous to admission, two years.

Form of insanity, primary dementia.

Family history, negative.

On admission the patient was very dull and stupid, untidy in habits, and had considerable diarrhœa. A physical examination showed that he suffered from a prolapsed rectum, which was said to have existed for one year. This was reducible by manipulation, but would return when the patient walked about, or with an attack of diarrhœa. During his residence in the hospital (fifteen years), the patient was almost continually confined to bed on account of the descent of the prolapse, when he would get up, as also because of the incontinence of fæces that would occur with the attacks of diarrhœa. Diarrhœa would be accompanied by mucus discharge, but never by any blood. Six months previous to operation the prolapse became irreducible.



On December 14, 1902, Dr. A. E. Macdonald, the Superintendent of the hospital, requested Dr. Joseph D. Bryant and Dr. William C. Lusk of the Consulting Board to examine the case. They did so, and a radical operation was recommended. It was proposed to make an incision through the anterior abdominal walls, reduce the prolapse by external manipulation, and anchor the sigmoid flexure by firm sutures to the anterior abdominal wall, and thus furnish an artificial support. Examination shows complete rectal prolapse, six inches in length, with sulcus at anal margin.

The figure shows the patient with the rectum prolapsed.

Preparation of the Patient.—The day previous to

the operation a complete physical examination of the patient was made. This failed to reveal any condition which might render the operation not justifiable. The examination of the urine resulted as follows: color and odor, normal; specific gravity, 1015; no albumin, sugar, or casts; uric acid and urates present, but not in excess.

The patient was placed upon an exclusive milk diet, calomel in one-half grain doses was administered every half hour until four doses had been taken. This was followed by two minims of croton oil in an ounce of castor oil, the object of which was to thoroughly empty the bowel.

The abdomen was shaved and scrubbed with tincture of green soap, followed by alcohol and ether, and then with a solution of bichloride of mercury. A bichloride dressing was then placed on the abdomen and allowed to remain twelve hours, when it was replaced by a dressing of sterilized gauze.

The day of the operation the patient was allowed no breakfast, or dinner, five copious enemata of soap and water were given and the bowel thoroughly cleansed.

Operation January 23, 1903, by Dr. Wm. C. Lusk.—One half hour before the administration of the anæsthetic the patient was given hypodermatically morphia sulphate grain $\frac{1}{4}$, atropia sulphate grain $\frac{1}{150}$, strychnia sulphate grain $\frac{1}{40}$.

The field of operation was rendered aseptic by scrubbing with a tincture of green soap and sterile water, after which alcohol and ether and bichloride solution were applied, followed by sterile water.

The incision passed through the left rectus muscle from a point about 1½ inches above the pubes upward for about five inches. The patient was put in the Trendelenburg position. A finger introduced into prolapsed cul-de-sac of Douglas determined an entire absence of adhesions at this situation. The depth of the peritoneal pouch extended to about one inch below the anal opening. The bladder was not prolapsed. The prolapse was now reduced with comparative ease by external manipulation. The outer intestinal tube showed considerable induration, but the invaginated portion presented a normal appearance. After reduction the rectum was drawn firmly upward by traction on the lower end of the sigmoid, after which the tension was eased off just a little, and the then lowest presenting portion of the sigmoid was sewed to transversalis fascia, as recommended by Dr. Tuttle, at the lower angle of the wound. The transversalis fascia at the seat of suture was bared by excising a little of the underlying peritoneum.

The method of suture was by interrupted stitches fastening each border of the transversalis fascia separately to the anterior longitudinal band of the sigmoid, thus leaving a V-shaped space between the edges of the fascia, through which the presenting portion of the bowel could gain an adhesion to the rectus muscle. One suture was placed at the lower angle of the wound in the transversalis fascia, and five others were inserted in either border immediately above it. All the sutures were of No. 1 ten-day chromic catgut, excepting the highest one on each side, which was of No. 3 silk. The length of the bowel sutured to the transversalis facia was about 1½ inches. The leaving of an area of bowel to unite with the rectus was similar to the method practised by Dr. Bryant who sutured the bowel into the abdominal wound.

The peritoneum and transversalis facia above the site of sigmoidopexy were united by a No. 1 continuous ten-day chromic catgut suture, and the remainder of the wound was closed by tier suturing. Sterile dressings were applied. The nates were strapped together with adhesive plaster. The foot of the bed was elevated and kept so for fourteen days.

The administration of the anæsthetic was begun promptly at 2.30 P.M. The first incision was made at 2.45 P.M., and the operation completed at 4 P.M. The patient was under the anæsthetic one and one-half hours, the operation proper lasting one and one-quarter hours. Nine ounces of ether were used. No stimulation was required. The patient reacted well from the effects of the ether and was able to answer ordinary questions in twenty minutes. There was a moderate amount of nausea for an hour and a half, accompanied once by vomiting. Cracked ice was given at frequent intervals.

Subsequent Treatment and Results.—Immediately following the operation, morphia sulphate grain $\frac{1}{6}$ was administered hypodermatically, and was followed by several hours of sound sleep. No food whatever was allowed until after twelve hours had elapsed. The temperature the following morning at 8 o'clock was $99\frac{3}{5}$, pulse 88, full and regular, respiration 18. For the next five days the patient received tincture of deodorized opium, minims 10, every four hours, the object of which was to confine the bowel and induce quiet. A restricted dietary was also ordered, and consisted of three pints of warm milk during twenty-four hours, two pints during the day and one pint at night, at intervals of two hours. On the evening of the fifth day, two ounces of olive oil were introduced by a Davidson syringe and soft rubber tube into the sigmoid flexure and two ounces into the rectum. The following morning the same procedure was repeated, and in addition drachm doses of equal parts of magnesium sulphate and rochelle salts were administered every half-hour until the bowels moved. After the administration of eight doses a soft movement from the bowels occurred unaccompanied by pain, and containing considerable mucus. For a week following this the oil injections were continued every evening and morning,and every other day the salt mixture was administered in drachm doses every half-hour until the bowels moved.

On the seventh day the abdominal wound was dressed and the superficial sutures removed. The deeper structures were in firm apposition, but a small quantity of pus was found immediately beneath the superficial sutures, but involving only the subcutaneous tissues. The finger introduced into the anal canal was grasped by the sphincters with a moderate degree of power.

The dietary at this time was increased to two quarts of milk in twenty-four hours, one and a half quarts during the day and one pint at night. The wound was dressed daily for the next week and began to heal by healthy granulation, after which the dressing was done every other day.

On the fourteenth day the patient was allowed solid food, commencing with gruels, soft boiled eggs, cornstarch and the like, in small quantities at first. As his general condition seemed to have suffered to some degree by the restricted dietary he was given cod-liver oil in one-half doses with tincture ferri chloridi, minims 15, three times a day. In addition to this strychnia, sulphate grain $\frac{1}{60}$ with spirits frumenti, ounce ½, every four hours. The latter being administered with the food.

Twenty-four days after the operation the patient was partaking of all varieties of solid food. The whiskey and strychnia were discontinued, bowels moved normally without enemata or salts and the wound was practically healed, although the dressing was still applied to guard against any possible

accident. He was, however, allowed to remain in bed a few days longer.

The patient being a dement, the temperatures were taken by axilla. The temperature the morning following the operation at 8 o'clock was 99⅘, rising in the evening at 6 o'clock to 100⅘, pulse 94, respiration 18. The next day the temperature at 8 A.M. was 100⅕, pulse 91, respiration 21; at 6 P.M. the temperature was 100⅘, pulse 93, respiration 22. After the dressing the temperature fell to normal and continued so with the exception that upon one occasion a slight rise occurred, which was attributed to an attack of indigestion.

At present writing, ten weeks after the operation, the patient walks about the ward with ease—not the slightest evidence of any return of the prolapse can be detected even when the patient is at stool.

The sphincter has perfectly regained its normal tone, the bowels move normally without enemata or laxatives, and there is no tendency to diarrhœa or constipation. The patient now goes to the closet of his own accord to attend to the calls of nature; he is less irritable, has gained in weight, and has been benefited in every way.

Clinical Department.

A CASE OF ADHERENT PLACENTA RETAINED AND DISCHARGED AFTER A LONG PROCESS OF DECOMPOSITION—RECOVERY.

By J. C. JOSEPHSON, M.D.,
BALTIMORE, MD.

On October 27, 1902, I was called to see Mrs. L., a Pole, about thirty-five years old, multipara. She had had trouble twice before with retained secundines during miscarriages, when she had also refused active interference and recovered. I found that the child had been born about one and a half hours before my arrival, but the placenta "had not all come off," as the good granny told me. In a slop pail by the bed I found the umbilical cord by itself which the granny had torn off, and some blood clots that she had taken for parts of the placenta. The woman was severely shocked. An attempt to deliver by the Credé method failed, and on inserting two fingers into the uterus I found the placenta firmly adherent by bands about three-quarters of a centimeter thick. An attempt to deliver manually was decisively resisted by both the patient and her friends, whether with or without an anæsthetic, or with or without additional help, on the ground that she was too weak, and that "she was going to die, anyway." The patient belongs to a class of old-world Catholics who are peculiarly resigned to the idea of dying, or rather prepared to die, on the least possible provocation in the way of ailment. It is, "He (or she) is going to die; call the priest." And this is said in the hearing of the patient, and the patient seems readily to concur. Especially in the case of labor the woman about to be confined presupposes that both she and the infant are in all probability going to die, and if either or both come out alive it is due to the great skill of the attendant, who is generally a midwife of most primitive qualifications. "Doctor," one of these said to me, "do you think I don't know what to do in similar cases? (we were talking about transverse presentations), "I rub in the belly with lard and oil and whiskey, and then either up or down it goes." In this case no amount of persuasion, warning, or even threats on my part would avail. As the patient was not bleeding at the time I thought I would wait for a few hours, and applied myself in the mean time to stimulating her with an intercellular saline injection, hypodermics of strychnine, brandy, etc., and when she had rallied to some extent I left her to attend to other cases. On returning late in the evening I found that the priest was with her, and when he was done I renewed my efforts to induce the patient and her friends to allow of active interference either by myself, or with the assistance of a brother practitioner. This was again strenuously objected to, and I was asked to wait until next morning. On the following morning the patient was in much better shape, but still declined to let me or anybody else do anything. "Doctor, the last time I had my miscarriage, the doctor also wanted to do what you would do now, and I wouldn't let him, and then he gave me powders, and from the powders it all came out of itself. Can't you give me the same powders?" There was the end of my patience, and I left her, warning her and her friends that she would get birth-fever and die. I did not see her again for four days. Then the husband came to me, begging me I should come and see her again, as she was very sick. I found that she had had a number of chills. Temperature 104°; pulse 160°; abdomen tense and painful (it had been greatly distended the day before according to accounts). The discharges were greenish and very fetid; in fact, the fetid odor struck you on entering the room. I advised again emptying the uterus with both hand and curette. This was again peremptorily objected to. "Give me something for the headache, something for the fever, and something for the belly-ache," the patient barely moaned out, and I was only allowed to insert two fingers, with which I dug out a lump of placenta and removed a few decomposed clots, following this with an intrauterine injection of a weak bichloride solution, which, by the way, I see specialists strongly object to. I refused to attend the patient any longer, thinking that she was certainly going to die, and I did not see her for two weeks. Then I was surprised to hear, on meeting her friends, that she was "getting better." Curious to know what had happened, I went over to see her. I found that she had had no medical attendant since I had seen her last. There was the same fetid odor about the patient, but her temperature was only 100°, pulse 120°, abdomen much softer and not so painful. She looked very weak, pallid and emaciated, just like a patient who had just been through the course of a severe septic fever. She told me that the placenta had been coming out in pieces, and on examination I removed a loosely-lying, decomposed, and very fetid piece of placenta with my fingers. The vaginal cul-de-sacs were very tender, and showed periuterine inflammation. I did not see the woman till three weeks later, when she was out of bed and apparently completely convalescent.

The Semi-Teetotal Pledge Association.—This association has adopted as its distinctive badge a button in the form of a large stud of enameled metal, on which is inscribed in red letters, "No Drinks between Meals." The *Hospital* remarks that, while the association has a membership of 1,700, it is not so sure that if the whole of the number parade the trade-mark of virtue by wearing a conspicuous badge, that courage will be imparted to the weaker brethren by so doing; possibly that may serve as a reason, but we doubt its efficacy. It will probably provoke that ridicule and banter which the weak cannot stand. After all, the movement is purely a matter of common sense and hygiene, and it will be a pity to endanger its principles by associating with fads and intolerance an association which has always stood in the way of teetotalism.

NON-OPERATIVE TREATMENT OF CHRONIC MAMMARY TUMOR.

By A. G. HENRY, M.D.,
CORTLAND, N. Y.

In August, 1900, I received a letter from a Mr. R. of the province of Ontario, Can., stating that his wife had a hard, rapidly growing tumor of the right breast, which had been diagnosed as malignant, and for which an immediate operation for removal was advised.

Mr. R., realizing the almost certainty of a return of the growth if excised—having lost a sister a short time previous from recurring cancer succeeding an operation for removal—wrote me if I would undertake Mrs. R's case.

As a result of my reply, he came with his wife on August 18, 1900. Mrs. R. was of medium height and weight, and light complexion. She was forty-seven years of age and the mother of one child—a daughter twenty years old. Her general health had not been good for some time, owing to dyspeptic troubles. Menstruation was regular and normal. The breasts were rather undersized.

The growth was situated about one and one-half inches to the outside, and a little above the right nipple. Its greater diameter was about one and one-half inches, its lesser one inch, and about the same in depth. It seemed attached to the chest walls. It was very nodular and very hard. There had been no injury received to the breast. Treatment was begun on August 19. At the end of the first week there was but little appreciable change in the size of the growth. At the close of the second week there was a very perceptible lessening in size. Progress was rapid from now on, and at the end of the ninth week the tumor had entirely disappeared. She left for home on October 21 in the best of health. There has been no recurrence of the growth up to the present time—now over two years. . . . Treatment consisted of electricity, locally applied, general body massage, with both deep and shallow friction movements to the lymphatic system generally.

Special attention was paid to movements in the vicinity of the growth, commencing with fine, almost imperceptible, touches over the tumor, and very gradually increasing the pressure upon leaving it. These movements were made away from the growth in all directions. Electricity was used daily for the purpose of stimulating absorption—dosage two to six milliamperes.

Phytolacca and thuja were practically all the medicines used, and these for their action on the lymphatics.

All flesh foods, as well as all foods in which flesh products were used (excepting butter, cream, and milk) were prohibited. Ere concluding I would state that for success in the treatment of all chronic affections requiring the daily use of massage and electricity, and a suitable dietary, the physician needs to have the patient at his own home or private sanitarium.

In the special work of dispersing mammary tumors, good judgment and considerable experience give the best results. As delicate a touch and as finely graduated pressure is necessary to success in working about a growth we wish to get rid of, as in manipulating pelvic adhesions and enlargements. Unskilful treatment is worse than no treatment.

A CLASSIFICATION OF INTRANASAL DISEASES FOR USE IN TEACHING.

By CARL E. MUNGER, M.D.,
NEW YORK.
ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL.

Whoever is in the habit of giving clinical instruction invariably remarks that the student is at all times prone to make his diagnosis offhand without taking into consideration the various pathological conditions of the different anatomical parts which go to make up a complex organ. In other words, to diagnose a single disease which might be present and ignore many times a much more important morbid condition present at the same time. I have noticed this, I might say, almost continuously while giving instruction in diseases of the nose and throat. The men who ever amounted to anything as diagnosticians were those who were willing to examine each part in detail, and determine the various lesions which might be present before arriving at a definite conclusion as to the name of a disease.

Recently, in giving a series of lectures on intranasal diseases, I determined to instill into the student's mind, if possible, the desirability of careful inspection of all the parts in detail, and prepared a classification of the diseased conditions arranged according to the regional anatomy of the nose, and which certainly formed a good working basis for both didactic and clinical instruction. This classification might have been more elaborately outlined, but was considered complete enough for practical teaching and study, and which is as follows:

- Internal Diseases of Nose
  - Mucocutaneous junction
    - Furuncle
    - Folliculitis alænasi
    - Eczema narium
    - Papillomata
  - Turbinates
    - Inferior
      - Atrophic
      - Hypertrophic
      - Purulent
      - Neuroses
      - Newg rowths
      - Membranous
      - Acute catarrhal
      - Mucous patches
    - Middle
      - Atrophic
      - Hypertrophic
      - Purulent
      - Neuroses
      - Polypoid degeneration
      - Cystic
      - Benign growths
      - Malignant growths
      - Membranous
      - Acute catarrhal
      - Mucous patches
  - Septum
    - Traumatic
      - Hæmatoma
      - Abscess
    - Deviations
      - Horizontal
      - Vertical
      - Oblique
      - Sigmoid
      - Dislocation of cartilages
    - Ecchondromata
    - Exostoses
    - Ulcerations / Perforations
      - Epistaxis
      - Crusts
    - Synechia
    - Mucous patches
    - Gumma
    - Caries and necrosis
    - Tuberculous deposits and ulceration
    - Hypertrophy
      - General thickening
      - Thickening of the erectile tissue of the vomer
    - New growths
      - Benign .. Papillomata
      - Malignant
        - Sarcoma
        - Carcinoma
  - Congenital defects and deformities
  - Foreign bodies, rhinoliths, and parasites

The Plague in Chile.—It is reported from Santiago de Chile that the bubonic plague has appeared at the seaport of Iquique, having been carried there by a ship bringing a cargo of rice from India.

A HINT IN URINARY ANALYSIS FOR GENERAL PRACTITIONERS.

By LOUIS FAUGÈRES BISHOP, M.D.,
NEW YORK.

In the physician's office laboratory two of the petty annoyances that he has to contend with in testing for albumin are dirty test-tubes and specimens that need filtration.

I have found the following plan a simple method of obtaining a clean test-tube and a clear specimen: Take an ordinary cotton tampon on a string, such as is used in gynecological work, push it to the bottom of a test-tube with a stick or glass rod and pack it in firmly Then pour the urine into the test-tube and pull out the tampon out very slowly by the string. This, on account of the atmospheric pressure, causes the urine to pass through the tampon and remain in the tube. The tampon carries out with it any particles that can be removed by filtration and at the same time cleans the inside of the test-tube. If there are several specimens to be filtered, the tampon can be rinsed under the faucet and used over again. I find by this method my test-tubes are always bright and clean inside, and there is none of the delay occasioned in using filter paper. The process can be repeated quickly two or three times if the first filtration is not satisfactory. In detecting very small traces of albumin, a perfectly clean test-tube is of great importance.

54 West Fifty-fifth Street.

Primary Sarcoma of the Appendix.—A case of this nature is reported by P. Peterson, his patient being a man of thirty-nine years with the usual history of pains in the right iliac fossa coming on at intervals, but causing no vomiting. The patient was seen in a severe attack of pain with slight fever and a mass distinctly appreciated in the fossa by palpation. A few days later, after acute symptoms had subsided, the abdomen was opened and the appendix exposed. It was found much thickened, firm to the touch, and bound down by adhesions posteriorly, whilst the omentum was coherent to its apex. The cæcum was also somewhat thickened for a radius of about ¼ of an inch round the attachment of the appendix. The adhesions were separated, and the appendix, together with the thickened part of the cæcum, was removed. The opening was then closed. The patient never rallied from the operation, and died a few hours later.

Careful post-mortem examination failed to show any trace of tumor formation elsewhere, and the part of the cæcum that remained appeared healthy. The appendix, on removal, was bent almost to a right angle and measured 16.5 cm. along the larger curvature, and 10 cm. in circumference at the thickest part. On microscopical examination the increase in bulk was found to be due to a round-celled sarcoma (Fig. 2) infiltrating all the coats with the exception of the peritoneal. The mucous membrane had almost entirely disappeared in parts, only the bases of the glands remaining. The neoplasm had evidently commenced toward the apical part of the appendix, and extended along the walls toward the cæcum; the small part of the latter that was involved showing very little infiltration.—*Practitioner.*

Shakespeare as a Medical Authority.—Some Shakespearian commentators would seem to consider the "myriad-minded" dramatist a sufficient authority on all matters necessary to man's existence. There is, however, a discriminating worship and discerning minds see in the wondrous portrayals of the great master a mirror, mysteriously polished it may be by the wonder-worker mind, which reflects in great measure the manners and opinions of his time. This is certainly the case as regards such medical matters as are dealt with by Shakespeare. Dr. John Knott, in the *Westminster Review*, has a luminous article on the medical knowledge of Shakespeare, in which this thought is admirably carried out. There are but few definite allusions to the anatomy and surgery of the skeleton. Of muscles as distinct entities in the framework of the human organism, Shakespeare appears to have had no knowledge whatever. His references to nerve and sinew are vague, and well indicate the indefinite ideas prevailing in his time. Regarding the circulation of the blood there are certainly many instances which seem to show that he had glimpses of some true knowledge, but it is quite certain that many anatomists and physiologists had at least conceptions of the truth before Harvey was born. It is of peculiar interest to note the references to venesection scattered through the plays. Shakespeare was keenly observant of the progress of physiological processes as indicated by his quoted studies on old age and approaching dissolution; but the science of pathology hardly existed in his day, and although we meet with references to rheum and certain other morbid states, there is but little of actual value in regard to manipulation of disease. The medical student would certainly do well to read his Shakespeare, but to appreciate fully its references to the healing art he should recognize the embryonic condition of scientific knowledge regarding the composition and constitution of the body which existed in the glorious Shakespearian age.—*Medical Press.*

Notes on Some Recent Advances in Ocular Therapeutics.—Cecil E. Shaw says that in eye work adrenalin has two distinct uses; one is to blanch the conjunctiva and so lessen bleeding in operations involving the cutting of that membrane, the other to reduce great conjunctival injection and so promote absorption into the eye. Acoin is a less well-known drug; its chief use in eye work is an addition to solutions for subconjunctival injections, of which it greatly lessens the pain. Protargol is less painful than the old solutions of silver, and not being precipitated by albumin it penetrates to all parts of the lachrymal sac. In troublesome cases of chronic conjunctivitis, however, the old nitrate of silver solution is, on the whole, more effective. Cuprol is well spoken of as a substitute for sulphate of copper, but the author has as yet had no personal experience with it. Euphthalmine is the most satisfactory mydriatic when we wish to dilate the pupil for ophthalmoscopic examination with the smallest possible disturbance of vision. The only disadvantage is its expense. Mydriasine has just been brought out by Squire. The author has had a sample for three days only, and so cannot give an opinion on it, but says that certainly one drop of a one-per-cent. solution causes full mydriasis in thirty to forty-five minutes, and in a case of suspected iritis it acted excellently, showing an adhesion of the iris to the lens capsule. Aspirin seems to act very well in affections of the eye due to rheumatism. Jequeritol and Jequeritol serum are said to be of use in cases of granular conjunctivitis with pannis.—*Medical Press and Circular.*

Chronic Diffuse Nephritis Unaccompanied by Albuminuria.—A. R. Elliott states that the presence of albumin in the urine in cases of chronic nephritis is uncertain, and that it consequently is but a very unreliable diagnostic guide. When present, associated with physical signs and other urinary indications, it serves to complete the diagnosis, and if absent, no inference is justifiable, and the diagnosis must be constructed without its aid. Much more reliable evidence of renal change is the lowered excretion of urea, which may exist months or years before the appearance of albumin, and especially important is the presence of tube casts in the urinary sediment. Casts are undoubtedly present with greater constancy in contracted kidney than is albumin, and in the diagnosis of this disease it may be stated that the morphologic evidence afforded by the presence or absence of casts may be accorded more weight than the existence or non-existence of albumin in the urine. While in the main they are associated, casts may frequently be met with when no albuminuria exists.—*Medical Examiner and Practitioner.*

New York, June 6, 1903.

THE STRONG DRINK SITUATION AND THE VIEW POINT OF THE ALIENIST.

ALMOST every country of the world is taking up the drink question. The authorities in some lands have become seriously alarmed at the inroads which the unbridled consumption of alcohol has made and is making into the prosperity, health, and morals of their people.

In France the unrestricted sale of alcoholic beverages has already brought forth dire results. Prominent French physicians have begun a crusade against the drink habit. In Russia the excessive drinking among the peasantry has impelled the Government to step in and take control of the sale of spirituous liquors. Although in America drinking has never been so common nor carried to such an extent as in Europe, yet even here statistics tell us that there has been a decided increase in the consumption of alcohol. Great Britain has always had an unpleasant reputation as a country whose people were addicted to strong drink on a large scale, and it still, in this respect, retains its position in the front rank. The situation, too, is at the present time aggravated, in that adulteration of beverages containing spirits is the custom everywhere. Too much of the genuine article is bad enough, but when in place of pure or comparatively pure spirituous beverages, vile concoctions are substituted, the evil is intensified in a corresponding degree.

Dr. Robert Jones, Medical Superintendent of Claybury Lunatic Asylum, London, published a short time ago a paper treating of drink with regard to the production of insanity. Referring to statistics bearing upon this matter, he said "There are probably at the present time no less than 110,000 certified insane persons in England and Wales alone, of whom approximately about 50,000 are males and 60,000 females. If the Lunacy Commissioners' Blue Book for England and Wales be consulted, the proportion percentage of instances in which alcohol has been assigned as the cause of insanity to the yearly average number admitted into asylums in the five years, 1895-1900 inclusive, is 21.8 for males and 9.5 for females—the proportion is much higher in Scotland—and after allowing for the deaths of those whose form of insanity is more immediately fatal than those caused by alcohol, there are, I believe, upon the lowest computation, remaining in asylums, at the present time, no less than 10,900 males and 5,800 females who are mentally decrepit through the effects of alcohol. During the time that the London County Council's Asylum at Claybury has been opened, from 1893 to the end of 1901—a period of less than nine years—8,493 patients have been admitted, of whom 21.2 per cent. of the males and 12.6 of the females were definitely ascertained to owe their insanity to drink, a total of over 800 men and 594 women who were thus rendered incapable of productive work through their own acts. For the whole of London, during the period 1893-1901, 2,662 men and 1,677 women were received into asylums who owed their insanity to alcoholic intemperance."

Chronic alcoholism, according to Dr. Jones, implies an altered nutrition of all the tissues, particularly parenchymatous elements and epithelium, such as that of the blood vessels—causing thickening and ultimately fibroid changes. It has been stated to be one of the special causes of dementia paralytica. It certainly is one of the most important elements in the strain which predisposes to this breakdown, and it is a most fertile source of nervous diseases. The degeneration of the tissues consequent upon altered nutrition is so general and far-reaching that the resulting symptoms are of a most protean nature. Attempts have been made to differentiate these according to the particular form of alcohol taken—such as wines, beers, spirits, liquors, etc.—but the distinction is less psychical than physical, and the symptoms consist in the greater frequency of convulsive discharges from such as absinthe, of analgesia from wines, and of hyperalgesia from essences. The liver of the spirit drinker is familiar, as also the gross fatty changes in beer-drinkers.

The writer points out that many different considerations present themselves in regard to symptoms, such as (1) the diathesis, idiosyncracy, or the inheritance of the individual. An inheritance of insanity is found in about 33 per cent. of all such cases admitted into asylums. A person of neurotic inheritance is predisposed to the incidence of delirium, small doses of alcohol giving rise to marked unsteadiness and other functional disturbances; in others the nervous system almost entirely escapes, and the stress is felt upon the liver and kidneys. (2) Sex appears to have a marked influence, for although alcoholic indulgence is most common among men, women recidivists are more common and less curable. (3) Elimination is a personal factor dependent upon the activity of the various excretory organs, such as the skin, kidneys, lungs, etc., in any particular individual. (4) Exercise appears also to influence the symptoms, as life in the open air favors tolerance. Both men and women of sedentary habits suffer in comparison to the more active, and the more frequent incidence of peripheral neuritis in women is probably due to their indoor life. (5) Age is a modifying factor. The period of greatest incidence to the pernicious effects of alcohol corresponds closely with that upon which falls the greatest mental strain. Males between twenty-five and thirty, and those between thirty-five and forty, appear to be—according to Bevan Lewis—more susceptible to alcohol than those of any other age. The former is a period peculiarly characterized by intellectual advance, and one during which the habits tend to become independent and fixed, the other is an epoch during which the struggle for existence makes itself felt in the fullest force, and it is also an age during which, as Lewis points

out, the feeble and indifferent organisms often feel the want of artificial stimulus, to the use of which they often succumb.

The relation between drink and insanity is far more intimate than it was at one time believed to be. Perhaps the assertion that drink is the most potent cause of mental disorders would now pass without cavil. Certainly the brain is the organ which is most disastrously affected by excessive indulgence in alcohol, for although other organs may be seriously injured, the outcome of the habit is more frequently mental dissolution.

PROFESSORS AND MEDICAL MEN AS TRUSTEES OF COLLEGES AND HOSPITALS.

Dr. W. W. Keen, in his presidential address at the Sixth Congress of American Physicians and Surgeons, which opened at Washington on May 12, dealt partly with this subject. The speaker said that there were two classes of institutions to be considered: (1) medical colleges and (2) hospitals, whether they be connected with medical schools or not. As to the qualifications of a medical man for a trusteeship of either of these institutions, there should be, in the opinion of Dr. Keen, but two questions asked of a professor or a hospital physician or surgeon: First, which one of the candidates for the place has the best qualifications from the medical point of view? This should include not only his scientific knowledge but his ability practically to impart or apply that knowledge. Secondly, are his personal qualifications and character such as to make him a desirable incumbent of the position?

With regard to the frequent clashing which occurs between the medical board and the board of trustees, the speaker thought that it was in many instances due to misconception of motives. The medical board and the board of trustees often seem to think that their interests are conflicting, whereas if they would endeavor to work together, it would soon be discovered that in truth the reverse is the case. One of the best methods of bringing the medical board and the board of trustees into more intimate contact would be to have the dean or a committee of the faculty, or, in a hospital, if the staff is not too large, the whole staff invited to the meetings of the board. "Here," says Dr. Keen, "I can speak from personal experience. At the Orthopedic Hospital and Infirmary for Nervous Diseases in Philadelphia there are three surgeons and three physicians. These members of the medical staff are invited to meet with the board of managers at each monthly meeting, excepting the annual meeting, when the medical staff is elected. They are free to express their opinions on any topic relating to the management of the hospital to which their judgment may contribute something of value, but when a decision is taken they have no vote. It is purely in an advisory capacity and for the purpose of giving and receiving information that they are present. The plan works exceedingly well."

The next point touched upon by the author is one of great importance, and concerning which the medical profession is by no means of one mind. This is the age at which boards of trustees shall retire college professor, or hospital physician or surgeon from the active duties of his post. There are some who hold that experience counts for so much that a man should keep his position, so long as he is able to get about at all, while others as stoutly maintain that such positions are best filled by young or comparatively young men. As a matter of fact, the truth lies in the mean, and, as a rule, a professor or member of a hospital staff should be neither young nor old. Dr. Keen believes that boards of trustees should fix a retiring age in the interests of the students and the patients. As age advances, a man s opinions and his practice become "as petrified as his arteries." He is incapable of constant study of adding to his knowledge or of keeping up with the feverish strides of medicine. If no rule exists, he is allowed to continue his inefficient or even disastrous work, or by some harsh suggestion is compelled to give place to another more competent man.

The following rules are in force in some of the larger institutions: At Harvard, the age when a professor may request to be retired is 60, provided he has been in the service of the university for twenty years, with a reduced pay ranging from one-third to two-thirds of his salary. At 66 he may be retired by the President and Fellows, partly or wholly. At Yale the retiring age is 65, after twenty-five years of service, and on half pay, but the retirement is not compulsory. At Columbia the retiring age, after fifteen years of service, is 65, either at the request of the professor or upon motion of the trustees, and on half pay. The only hospitals in the United States in which a retiring age is fixed are the Massachusetts General Hospital and the Boston City Hospital. At the former the compulsory retiring age of the surgeons is 63, and of the physicians 65. At the Boston City Hospital the visiting surgeons are retired at 65, but the physicians, gynecologists, and all the other medical officers continue in service indefinitely. The author is strongly of the view that an age limit of 65 should be compulsory, and so not be invidious in any given case.

As to whether there should be a certain number of doctors on the board in hospital and college management, Dr. Keen believes that a small proportion of well-chosen medical men is a distinct advantage in such boards of trustees. By a "small proportion" he means not more than 20 per cent. Such medical men should be selected for trustees by their mental training, social relations, and personal character would be, so far as it is possible for human nature to realize such a position, absolutely free from influences arising from personal jealousy or professional bias.

The question of having medical men on the board of trustees of hospitals has been discussed with much bitterness on more than one occasion in Great Britain. In one London hospital in particular the trustees and medical staff came to an open rupture, and the affairs of the institution and the quarrelings of the rival factions were published at length, in both lay and medical journals. The upshot of the matter was that public opinion showed itself in favor of medical men having some voice in the management of hospitals. This, indeed, is the only reasonable way of regarding the question. An entirely lay board of management can, if its members so wish, hamper the action of the medical staff to

the detriment of the patients. There should then, as Dr. Keen urges, be a certain leaven of medical men on the boards of trustees of all public medical institutions not sufficient to leaven the whole mass, but enough to make its influence felt.

EDUCATIONAL REQUIREMENTS FOR ADMISSION TO A MEDICAL COLLEGE.

The raising of the standard of medical education throughout the United States, so that it may be placed on a uniform basis, is the fondest hope of the medical reformer. Matters in this direction, if not travelling apace, have at least made satisfactory progress. With this consistent and uniform elevation of the standard of medical education, the raising of the standard of preliminary education in arts must go hand in hand. The time has passed forever when a man deficient in general knowledge can enter upon the study of medicine. It is freely allowed that a certain amount of knowledge and even of culture is necessary in these days for the full equipment of a medical man. As to what should constitute the minimum requirements for admission to a medical college, has not, as yet, been clearly defined, nor settled by the unanimous decision of the best-known authorities on educational affairs.

Dr. William H. Wathen, Professor of Obstetrics, Abdominal Surgery, and Gynecology in the Kentucky School of Medicine, Louisville, delivered an address before the Association of American Medical Colleges in New Orleans, May 4, in which he dealt with the above question at some length. The first part of the article is taken up with a comparison of the systems of education in vogue in England, Germany and France, and the United States, showing that, upon the whole, the advantage in educational methods lies with this country. Dr. Wathen thinks it will be concealed that in European countries but few pupils can be properly educated for admission to professional schools except through colleges and universities, while in the United States they can be well prepared in our free public schools. Whereas, however, as the curricula in the primary, intermediate, and secondary schools differ, not only in various States, but even in the different schools of each State, both in time and in amount and character of work required, the speaker opined, that we should, in accepting a high-school diploma as a minimum qualification for admission, correctly understand and determine the time requirement, and in a general sense the amount and character of education given—being liberal in the allowance of electives. In view then of the fact that most of our States and cities in which the public-school system is encouraged and fostered require an attendance of twelve years of not less than forty weeks each from the beginning of the primary to the completion of the secondary course, the association should finally expressly provide that the diploma of no high school obtained in less time shall be accepted as a minimum requirement for admission to a medical school.

Dr. Wathen next proceeded to criticise the attitude of our well-known universities in respect to the shortening of the period of university residence. These universities, or at any rate a few of them, combine to a certain extent literary and medical work, so that it is possible to obtain a degree in arts and in medicine in within six or seven years, or, under exceptional circumstances, in five years. It may be said that Oxford and Cambridge pursue a somewhat similar method. As to the subjects to be studied to best prepare a man for his medical course, the speaker is of the opinion that the study of too much mathematics, as also some of the collateral sciences, should be discouraged, the time would be better consumed in a careful study of English and Greek and Roman history, and in the life and growth of language, especially of the philology of the languages that may be traced to an Aryan or Indo-European origin. Says Dr. Wathen, "Of all languages, except our native tongue, the study of Latin is of the greatest value, and, excluding the commercialism of German and French, Greek should be next in order, for even an imperfect knowledge of these two languages will enable the student easily to understand the etymology of the many compound technical terms in the study of medicine, which a knowledge of no other language will do. German can never be of much value in the study of the rich scientific literature of that language, unless it can be read with ease and correctly translated, and this cannot be done by the American student of four years' study of five hours a week in our high schools. Again, in the near future, all that France or Germany may discover or develop, if of real value, will be promptly given to us in a translation by scholars educated in German or French, English and the Sciences; and even to-day we find many such translations in libraries throughout the country."

Finally the speaker suggested that the association of medical colleges should be urged not to give time credits for work done, except in a recognized medical college, and to insist upon a discontinuance of the combined academic and professional courses. He also advanced the proposition that it might be found necessary to reduce the academic and arts course to three, and probably to two, years.

The true stumbling block in this country, to the attainment in every part of it of a thorough medical education, is the lack of a uniform standard. The best universities perhaps ask too much of its medical students, while there are too many universities and medical schools which most certainly ask too little. Of course a four years' medical course is a *sine quâ non*. Indeed, it is an open question if this period be sufficiently long. However, there can be no doubt that no time credits for work done should be given except in a recognized medical college, and it might be as well to shorten the academic and arts course in the universities to three years. What is needed above all is to have a uniform high standard of medical education in every State in the country. The requirements for entrance to a study of medicine should also be demonstrative of the fact that the would-be medical student has received a liberal education, that he has a fair knowledge of Latin, and, if possible, also of Greek and German. There is no reason, so far as can be judged, why more time should not be given to the study of German. A reading knowledge of German is of infinite service to the medical man, and in spite of the statement of Dr. Wathen that translations, of that language answer the purpose well enough,

we feel more or less confident that to be able to read the language with some degree of facility is an immense advantage to the man who desires to keep abreast of the best scientific literature. A fitting slogan for the American medical profession would be "Make a uniform high standard of medical and literary education throughout the country."

The Bacteriological Impurities of Vaccine Virus.

The superlative importance of procuring vaccine virus as free from impurities as possible, is so obvious as to require no emphasizing. The prejudice which has existed for long years against vaccination has mainly risen from the use of lymph which contained harmful microorganisms. Consequently the object of medical men—especially of those versed in laboratory work—has been to discover a method of preparing vaccine virus which shall practically render it safe.

Dr. Monckton Copeman claimed to have reached this end when he devised the method of mixing the pulp with the best quality of sterile glycerin. Glycerinated calf lymph has now had about twelve years' trial, and, in the opinion of the majority of medical men in Great Britain, in Germany, and in this country, has stood the test remarkably well. But nevertheless there have been numerous accidents even when using this preparation, and latterly several laboratory workers have been seeking the cause of these iunfortunate occurrences.

Dr. Milton J. Rosenau, Director of the Hygienic Laboratory of the Public Health and Marine Hospital Service of the United States, has recently issued a bulletin describing his investigations with regard to the bacteriological impurities of vaccine virus. The experiments carried out at the above laboratory seemed to have been sufficiently exhaustive, and the conclusions reached are necessarily of much value. Some of these are as follows:

The vaccines of ten different manufacturers were examined during a period of more than a year. Of 190 dry points examined, an average of 4,354 bacteria per point were found. Of 244 tubes of glycerinated virus examined, an average of 1,742 bacteria per tube were found. A number of these capillary tubes contained over 10,000 bacteria, and one as high as 30,000. This is. of course, much more than a carefully prepared glycerinated virus should contain. The pus cocci and other bacteria, pathogenic for laboratory animals, were found in both the dry points and the glycerinated virus. The investigators demonstrated that some of the glycerinated virus marketed during the winter of 1901–2 contained an excessive number of bacteria, which decreased notably after a few weeks, indicating the sale of a "green" or unripe product; that is to say, the virus was not glycerinated a sufficient length of time before it was sold. It was also made plain, from the studies of Dr. Rosenau and his co-workers, that too much confidence was placed by the producers in the germicidal power of glycerin. The excessive impurities found in some of the glycerinated virus upon the market was believed to be largely due to this over-confidence in the germicidal value of glycerin. Glycerinated virus, when properly prepared and kept a sufficient length of time, is freer from impurities than dry points with fresh "lymph" There is practically no vaccine on the market free from bacterial contamination, although the product of some manufacturers is remarkably pure.

It would seem then that the moral to be extracted from the foregoing statements is that the germicidal action of glycerin is much exaggerated, and that greater care is needed in the manufacture of vaccine virus. The introduction of glycerinated virus, although a great advance on former methods of preparation has by no means rendered vaccination a perfectly safe procedure. Excessive precautions must yet be taken to so free vaccine virus from bacteriological impurities that it will be, to all intents and purposes, harmless.

Increase of Lunacy in Scotland.

The annual report of the British Commissioners in Lunacy shows that the number of insane in Scotland is increasing almost by leaps and bounds. In earlier years the recurrent increase in annual percentages might be explained as the natural result of the efforts put forth to bring the cases of existing insanity under official cognizance. Now, however, this excuse will not stand. Lunacy is increasing at a rapid rate, and the fact is obvious that lunatics are being manufactured. There are curious features in regard to the increase of insanity in Scotland, which seem to upset established notions as to its causation.

The Edinburgh *Evening Dispatch*, referring to the matter, says: "The annual report of the Lunacy Commissioners for Scotland offers ample and attractive material for the propounder of paradoxes. How is it that in the sober, clean-living, and easy-going northern and insular districts lunacy should be so much more prevalent than in the southern districts, where drink, and vice and crime, and bustle, and every sort of offence against good living, so much more abound? The facts seem to defy the most plausible theories. We have Dr. Clouston telling us in each annual report of Morningside Asylum that drink is one great outstanding cause of the lunacy with which he is called upon to deal, and yet when we widen the basis of observation, we find that lunacy is most prevalent in the soberest districts of the country. The Lunacy Commissioners themselves only obscurely hint at possible reasons for this paradox. The theory of intermarriage seems quite inadequate. If we take the island of St. Kilda, we have a community of seventy or eighty persons who have been intermarrying for generations, and in the memory of man have not furnished a single case of insanity. A much more formidable cause is probably the constant drain of the healthiest and most vigorous part of the population from the outlying to the industrial centers, with the result that in these outlying districts the renewal of the population is largely left to the least fit. Possibly there are other and more superficial reasons. A wag of a doctor in Skye used to allege that in that island insanity was mainly due to Free Kirkism and strong tea. The strong tea, he argued, produced chronic indigestion and melancholia, and Free Kirkism completed the ruin." There probably is a certain relationship between a disordered stomach and a disordered mind, and sensational religion is apt to overturn the mental balance of those whose minds are somewhat weak, but as causes of insanity, dyspepsia and religious fanaticism are not the most important factors. The position of affairs in Scotland as regards the class of individuals most subject to insanity deserves the close attention of alienists.

Transmissibility of Human Tuberculosis to Cattle.

Great differences of opinion still exist as to the possibility of transmitting human tuberculosis to members of the bovine tribe. Koch and his large following hold that the disease in man and in cattle

is distinct, and that consequently there is no reason to fear that the human race may contract tuberculosis from drinking the milk derived from a cow afflicted with the malady. There are, however, a very large number of scientific men who have by no means accepted the dogmatic statements of Professor Koch, but who have conducted careful experiments in order to prove the disputed point one way or the other. Among these the Americans, Ravenel and Salmon, have been foremost, both of whom have summed up enough to show that under certain conditions human tuberculosis can be transmitted to cattle. The most recent investigators into the matter are Professor Hamilton and Mr. M'Lauchlan Young of Aberdeen, who, after making a series of exhaustive experiments, arrived at the following conclusions: (1) That although human tuberculosis is probably not so virulent for the calf as that derived from bovines, yet it can be readily inoculated upon that animal. (2) That this holds good whether the tuberculosis inoculated be derived from tuberculous lymph-glands, tuberculous lung, tuberculous sputum or urine. (3) That it produces this positive result, irrespective of whether it be introduced by feeding the animal with the tuberculous material by subcutaneous inoculation upon a peripheral part, by respiring a spray containing the bacillus, or by infection into the venous system. (4) That the organs most affected are those in immediate connection with the part operated upon. (5) That the lymphatic system is constantly involved in the resulting tuberculosis. (6) That when administered by the mouth, tuberculous sputum induces an abdominal lymph-gland tuberculosis, without the intestine being necessarily involved in any way. (7) That when tuberculosis from a human source has been ingrafted upon a calf, it gains enormously in virulence by being reinoculated upon a second calf. (8) That the morphological characters of the bacillus may vary according to circumstances, and are no guide to the source of the organism under observation. (9) That the above facts go to favor the view that the human bacillus and that of bovines are identical, but modified somewhat by their environment. (10) That our results are a direct contradiction to those alleged to have been obtained by Koch and Schütz.

The foregoing conclusions, taken in conjunction with those of many other investigators who, since Professor Koch's announcement, have undertaken experiments on the subject, lead one to think that the German scientist must be mistaken, and that, in fact, human tuberculoses can be transmitted to cattle and *vice versa*. At any rate, no precautions regarding a pure milk supply should be relaxed, but rather every effort should be put forward by municipal authorities and health boards to ensure to the public at large milk as free from contamination of any kind as is possible.

The Combat against Tuberculosis.

The Committee on Tuberculosis of the Charity Organization Society of the City of New York has published an address delivered under its auspices by Dr. S. A. Knopf on February 9, 1903.

The speaker treated of the duties of the individual and the Government in the combat against tuberculosis. The whole subject was ably dealt with, all precautions against contracting consumption being discussed in detail. Speaking of the duties of municipalities with regard to combating tuberculosis, Dr. Knopf said: "Each city should have an efficient committee on tuberculosis, composed of a number of general practitioners, health officers, and trained charity workers. This commission should have its offices in a building connected with a special dispensary for tuberculous patients. Each patient applying should be carefully examined for the following purposes: (1) To determine the applicant's condition by medical examination. (2) To visit his home if he has been found tuberculous, and to institute such hygienic measures as seem necessary. (3) To examine the other members of the family, in order to find out if any of them have also contracted the disease, and, if so, to counsel proper treatment. (4) To report in full to the sanitary authorities concerning the condition of the patient's dwelling. Its renovation, or even destruction, may be imperative when it is evident that tuberculosis has become "endemic" there, owing to the condition of the soil or to other sanitary defects. (5) To determine the financial condition, whether the patient is or is not able to pay, and whether or not by his being taken to an institution the family will become destitute. If the latter should be the case, it would be necessary for provision to be made in some way for the family. In many cases a letter of inquiry sent to the former medical attendant of the patient would materially aid in the work of the investigating committee.

Dr. Knopf defines the duties of the State Government as follows: "Our State legislators should do their utmost to enact such laws as will secure always proper ventilation and light in public and private buildings. How necessary such laws are you will believe when I tell you that there are in Manhattan over 200,000 and in Brooklyn over 125,000 dark interior rooms without a window of any kind and having no means of light and ventilation." Without the earnest coöperation of municipal and State governments, little can be done in the fight with tuberculosis. With the aid, however, of the authorities in the States and cities, there is reason to hope that the campaign against consumption may be brought to a successful issue.

Blue Electric Light in the Treatment of Neuralgias.—Gabriele Arienzo applied this treatment in six cases with excellent results. The apparatus used consisted of a bell-shaped reflector, large enough to converge all the light from a lamp of thirty-candle power. The patient was placed about 15 cm. from the lamp; the duration of the treatment was from ten to fifteen minutes. The author concludes, from the results obtained, that the blue rays penetrate to the deeper tissues and reach the organs beneath. They are endowed with marked anæsthetic properties, which fully justify their use experimentally in neuralgia. The action is probably due to changes in the circulation induced in the afferent and efferent blood vessels of the nerve, or else to some specific action of the blue light itself.—*Annali di Elettricità Medica e Terapia Fisica*

Are There Variations in the Course of the Facial Nerve Having Bearing upon the Mastoid Operation?—B. Alex. Randall calls attention to the necessity of careful avoidance of injuring the facial nerve. If it were possible by watching for twitchings of the face, as is sometimes claimed, to get timely warning that we are approaching it dangerously, we might rest on this precaution, but he is sure that severe and persistent injury is too often inflicted unheralded by any such warning. Hence arises the absolute necessity of knowing the exact anatomical relations of the nerve. Randall teaches that the descending portion of the facial canal is almost exactly vertical and forms one of the most constant features of the temporal bone. The nerve crosses the oblique plane of the drum-head some 3 mm. back of the plane of the posterior margin of the annulus. Therefore in removing the back wall of the meatus we should aim to cut a little below the tympano-mastoid suture in order to be sure to remain in safe territory.—*Archives of Otology.*

News of the Week.

New York Infant Asylum.—Dr. Edwin B. Cragin has been appointed consulting obstetrician to this institution, in the place of the late Dr. T. Gaillard Thomas.

College of Physicians of Philadelphia, Section on General Medicine.—At a stated meeting, held May 18, Drs. J. Alison Scott and Robert LeConte reported a case of purulent pericarditis and exhibited the patient. Aspiration was first performed to evacuate the fluid accumulated in the pericardium, which, at this time, was almost clear and contained pneumococci. Later the fluid became purulent and part of a rib was exsected, the pericardium incised, and the pus permitted slowly to escape. The result was eminently satisfactory, the patient making a slow but perfect recovery. Drs. Joseph Sailer and Joseph S.Evans reported a case of infection with the colon-bacillus simulating typhoid fever. Dr. Thomas L. Coley presented a case of splenomegaly with enlarged liver. The man gave a history of malarial fever during many successive years, but plasmodia were not detected in the blood. There was a slight reduction in the number of red blood-corpuscles, a moderate reduction in the hæmoglobin percentage, and no deviation in the number of leucocytes. There had likewise been no hemorrhage from the mucous membranes.

Association of Medical Librarians.—The sixth annual meeting of the Association of Medical Librarians was held Saturday, May 16, 1903. A large number of librarians and physicians, representing the medical libraries throughout the country, assembled in the morning at the Library of the Medical Society of the County of Kings, Brooklyn, N. Y., and, after an inspection of the building, were entertained at luncheon at the Union League Club by the local members, Dr. Wm. Browning, Dr. J. M. Winfield, and Mr. A. T. Huntington. The scientific session was held in the afternoon, at the New York Academy of Medicine, the President, Dr. Wm. Osler, in the chair. Papers and discussions were contributed by Mr. C. P. Fisher of Philadelphia, Dr. T. G. Lee of Minneapolis, Mrs. G. W. Myers and Dr. E. H. Brigham of Boston, Mr. J. S. Brownne and Dr. W. S. Dennet of New York, Mr. A. T. Huntington of Brooklyn, and others. The officers elected for the ensuing year were as follows: *President*, Dr. William Osler of Baltimore; *Vice-President*, Dr. Abraham Jacobi of New York; *Secretary*, Mr. Albert T. Huntington of Brooklyn; *Treasurer*, Dr. George D. Hersey of Providence; *Executive Committee*, Mr. John S. Brownne of New York, Mr. Charles P. Fisher of Philadelphia, Dr. James M. Winfield of Brooklyn; *Manager of the Exchange*, Miss M. C. Noyes of Baltimore. The next meeting will be held in June, 1904, at Atlantic City, N. J.

Eleventh International Congress of Hygiene and Demography.—The following Committee of Organization for the United States, for the Eleventh International Congress of Hygiene and Demography, to be held in Brussels, September 2-8, 1903, has been appointed, at the request of the Belgian Government, by the State Department: Drs. E. A. de Schweinitz and A. B. Richardson, the Columbian University, Washington, D. C.; Dr. John Marshall, University of Pennsylvania, Philadelphia, and Dr. Harrington, Professor of Hygiene, Harvard University, Boston, Mass. The committee desires to secure the co-operation of all those in this country who are engaged in hygienic work, both in attendance at the meeting in Brussels and in sending papers to the Congress. The Congress will be divided into two sections, (1) Hygiene, and (2) Demography The subjects which will be considered are the relation of bacteria and parasites to hygiene, the hygiene of foods, the treatment and prevention of communicable diseases, etc. The important subject, in its various phases, of the communicability of tuberculosis will be discussed by prominent men. The fee for membership is 25 francs, which may be sent to the Secretary-General, M. le Dr. Felix Pulzeys, Rue Forgeur, 1, Liége, Belgium. Those proposing to attend or send papers are requested to notify Dr. E. A. de Schweinitz, Washington, D. C.

Campaign against Tuberculosis in New Haven.—The New Haven Medical Association has begun an organized and systematic anti-tuberculosis campaign in that city, and purposes to enlist the help of all public-spirited citizens, those who think and do things in the community, both lay and medical. One feature of the campaign will be a series of lectures of a popular nature, the first of which was delivered on Friday last by Dr. S. A. Knopf of New York.

The Maine Medical Association.—The semi-centenary of this society was celebrated at Portland on Wednesday, Thursday, and Friday of this week, January 3, 4, and 5. The President's address, which was devoted to the history of the association, was delivered by Dr. Hunt of Greenville on Wednesday afternoon. On Thursday evening the annual banquet of the association took place at the Lafayette Hotel. Friday was devoted to an excursion among the islands of Casco Bay and a "shore dinner." The medical history of Maine outside of the association, was treated of in two papers by Drs. J. L. M. Willis and Willis B. Moulton, the former reviewing the period from the settling of the State to 1853, the latter from 1853, the year of the foundation of the association, to 1903.

A Stain for the Gonococcus.—A misprint occurred in the third line of the formula for this stain, published on page 844 in the issue of the MEDICAL RECORD for May 23. The word written was chionin, two letters having dropped out in the form before printing.

An Osteopath Bill Vetoed.—Governor Yates of Illinois has vetoed a bill recently passed by the Legislature of that State, aiming to give a special status to osteopaths. The bill provided for an examination in "osteopathy" of all candidates who might have been in attendance for a specified time in an osteopathic college. The act also provided for the appointment by the State Board of Health of an examiner, who shall be a graduate of a recognized college of osteopathy and who should examine applicants upon the theory and practice of osteopathy. The Governor objected to these additions as being unnecessary, the present law providing for "the examination of those who desire to practise any other system of treating human ailments who do not use medicines, internally or externally, and who do not practise operative surgery." Under this provision the State Board of Health has examined and licensed over 350 osteopaths, not as osteopaths, however, but as licentiates empowered to practise osteopathy or any other system of treating human ailments, without the use of medicine or surgery, they see fit. The specially objectionable feature of the bill, however, was, that it compelled the State Board of Health to grant a license to practise to every osteopathist who should have been a graduate of a regular college of osteopathy, and who should have been practising in the State on the first day of March, 1903, who should be recommended to said Board by the Executive Committee of the Illinois State Osteopathic Association.

The New York State Board of Charities.—At the meeting of this Board, held in New York City, on May 27, the resignation of President William R. Stewart, which had been laid on the table at the annual meeting in April, was accepted at his urgent request. Commissioner E. V. Stoddard of Rochester, formerly Vice-President of the Board, was unanimously elected President, and Dr. Stephen Smith of New York City was unanimously elected Vice-President. The Board approved plans for the construction of a hospital for consumptives at the Westchester County Almshouse, and voted to appoint William C. Rogers of Rochester Inspector of Almshouses in place of Inspector Dorr, resigned.

Dr. James R. McLane has resigned as dean of the College of Physicians and Surgeons, the Medical Department of Columbia University, in this city. Dr. McLane was actively connected with the College as Professor of Materia Medica and Therapeutics, Professor of Obstetrics, and Dean, for more than thirty-five years.

Dr. Norman M. Harris, associate professor of bacteriology at the Johns Hopkins Medical School, has accepted a call to the University of Chicago.

The New York State Hospital for Crippled and Deformed Children.—Under the Supply Bill recently approved by Governor Odell and making an appropriation of $50,000, steps are being taken to secure a new site for the New York State Hospital for Crippled and Deformed Children, now situated at Tarrytown. A committee of the Board of Managers had several sites under consideration, all in Westchester County. Immediately on their choice of a site a suitable hospital building will be begun.

Collision between an Electric Car and an Ambulance.—While responding to an ambulance call from Lexington Avenue and Thirty-second Street, one evening last week, a Bellevue Hospital ambulance driven by Patrick Devens, in charge of Dr. Warren, was run into by a northbound Third Avenue car at Thirty-second Street and was almost demolished. Dr. Warren was thrown from his seat and landed on his head against an elevated pillar. He was unconscious when picked up and had a badly lacerated wound of the scalp. Devens was badly bruised. The horse's leg was broken and the animal was shot.

Obituary Notes.—Dr. A. Tagert of Chicago died of pneumonia on May 27, at the age of fifty-seven years. He was a graduate of the Medical Department of the University of Vermont in 1866, and had practised in Chicago for thirty years. He was President of the Kedzie Hospital.

Dr. G. P. Andrews of Honolulu, H. I., died May 9, 1903.

Dr. James C. Channell died at Wrightsville, York Co., Pa., on May 19, at the age of sixty years. He was graduated from the Medical Department of the University of Pennsylvania in 1871. He served during the Civil War as Lieutenant in the One hundred and ninety-fourth Pennsylvania Regiment.

Dr. John Gosman died at Doylestown, Pa., on May 24, at the age of seventy years.

Dr. T. C. Rich died from appendicitis at Williamsport, Pa., on May 27. He was graduated from Jefferson Medical College in 1887.

An Improved Means of Using Salicylic Acid.—W. L. Johnson reports a number of cases in which aspirin, an acetyl derivative of salicylic acid, was used with excellent results. Severe headaches have been relieved, as well as the pains of rheumatism, dysmenorrhœa, grippe, etc. The main advantages of this drug are that it does not, like the salicylates, irritate the stomach, and that it only rarely gives rise to tinnitus or other by-effects of the other drugs.—*Massachusetts Medical Journal.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS—CONVALESCENTS AND THE PARKS—LIVERPOOL'S NEW LABORATORIES—CRITICISM—RHEUMATISM AND MICROBES—KING SANATORIUM—ANTI-VIVISECTIONISTS AGAIN—DEGREES FOR DENTISTS—EDINBURGH'S NEW HOSPITAL.

London, May 15, 1903.

Great efforts are being made to secure second collections of all three hospital funds for this year. The Lord Mayor presided on Wednesday afternoon at a meeting of the Council of the Sunday Fund. The report stated that the King and Queen would attend the service at St. Paul's Cathedral on June 7, which is appointed as Hospital Sunday this year. The Dean has been approached as to the appointment of about ninety stewards, who are to give a donation of 30 guineas each and of 20 guineas if similar services are held in future years. A letter was read from that magnificent supporter of the fund, Mr. George Herring, making the same offer as last year, viz., either to present a check for £10,000 or to add one-quarter to the amount collected in all places of worship, but as so much energy is being shown this year he must limit the amount to £100,000, so that if the collections exceeded that sum, which he sincerely hoped it would, his own donation would be only £25,000.

No wonder this statement was received with cheers. Then came a letter from Mr. A. Herring, asking for two seats, and requesting the Lord Mayor to put his name down for £1,000.

His Lordship said he hoped this historic year the hospitals would receive £250,000 from the three funds—£100,000 from King Edward's fund, as much from this Sunday fund, and £50,000 from the Saturday fund.

The County Council has adopted the principle that any of the unused houses in the parks under its control may be used as convalescents' homes, if suitable for the purpose, and if no legal obstacle prevent. This plan has been before the public ever since the Guards invalided from South Africa were accommodated at Golden's Hill. Objections were felt at the time but were not pressed, as that was a temporary measure. Since then the question has been discussed with considerable warmth, which was duly reflected in the Council when the subject came up last week. Owners of property in the neighborhood fear that such use will cause depreciation, or that infectious cases will be ultimately admitted. Others fear that the County Council is desirous of municipalizing the hospitals, and that this proposal is favored as a step in that direction.

Infectious diseases are dealt with by the Asylums Board, and it is not at all probable that any such would pass to the proposed homes in the parks, which would be devoted to convalescents from the hospitals, especially children. Sir W. Collins said the "lungs of London existed for health and recreation," and admitted that probably the recreation had been overdone, and that health now demanded more attention. This was a fair hit at the suggestion to set up a municipal music-hall. Another equally preposterous proposal was to devote a part of the Golden's Hill Mansion to the residence of the park constable! It was actually proposed to instruct the architect to prepare plans for alterations for this purpose. Other proposals were refreshment rooms, public conveniences, and so on.

Really, convalescent homes would seem more fitting than these. But there was no need for the temper displayed by some of their advocates—one clerical defender professing to "despise the selfishness of wealthy opponents," ignoring the fact that these wealthy persons had contributed largely to the purchase fund, on the express understanding that the park was only to be used as an open space.

Liverpool may well be proud of her wealthy citizens. Another of them has directed his munificence to the encouragement of medical research. Mr. William Johnston has erected and equipped laboratories of such importance that Mr. Long, President of the Local Government Board, went down to Liverpool on Saturday last to open them. In formally declaring them open, Mr. Long dwelt on the close connection between the development of science and especially of preventive medicine and commerce. One of the objects of these new laboratories, he was informed, would be to increase knowledge concerning vaccines, sera, or any preventives of disease. Such work, from the point of view of commerce or of government regulations as to diseases, must be of the greatest advantage to the country as a whole. Alluding to the proposal to establish a separate university for the city, he

complimented Liverpool on having contributed some £200,000 to the fund, and on the further epoch-making incident that their city was willing to be rated for the purpose of maintaining university training. "Peace hath her victories as well as war" might be rightly the motto for large-hearted citizens like Mr. Johnston. Might his benevolent work have great triumphs in saving human life!

Principal Dale proposed and Sir Alfred Jones seconded the vote of thanks to Mr. Johnston for his munificence and to Mr. Long for opening the buildings. Sir Alfred said he believed the King of the Belgiums would shortly visit the School of Tropical Medicine, to which his Majesty was a generous contributor.

The new buildings thus hopefully inaugurated are 90 feet long and adjoin the Thompson-Yates laboratories. There are four floors, devoted to separate departments, each under its own professor. Comparative pathology under Dr. Annett occupies the basement. Tropical medicine the ground floor under Professor Ross. Other departments are physiology, pathology, biochemistry, and cancer research—the last under Dr. Grunbaum These Johnston laboratories are the first that have been erected in this country to be devoted exclusively to research work in biochemistry. The general supervision will be undertaken by Prof. B. Moore, who will occupy the Johnston chair of biochemistry.

Some interesting facts relating to cretinism were mentioned at the pathological society last week, when Dr. C. G. Seligmann read a paper on the condition in calves. He said that in every herd of Dexter Kerry cattle observed in this country a number of monsters were born, the type being constant; in fact, these calves were cretins. The deformity has not been observed in other breeds. The condition arises in fetal life, and is associated with a diseased state of the placenta. Out of eighty-two calves nineteen of these showed the characteristic short basis cranii, short limbs, etc., and in all the thyroids which were examined there was absence of colloid, with the usual malformed or ill-developed vesicles, choked with more or less spheroidal cells. Œdematous changes were noted in the placenta extracts of those thyroids caused no fall of blood-pressure. Dr. Andrews suggested that the condition of these thyroids was allied to achondroplasia, though he had never found in that disease such a condition of the thyroid. Mr. Shattock said the condition of these calves was just like that produced by the removal of the thyroid in young animals. Removal of the gland in the pregnant mother did not affect her, but it was found that the gland of the fœtus hypertrophied, as if to supply the maternal defect. Perhaps the disease of the placenta prevented such interchange, or, possibly, the cows of this herd were themselves in a sub-cretinoid state. Otherwise it was not easy to explain the facts. In reply to this and other questions, Dr. Seligmann said there was no evidence of a sub-cretinoid condition of the cows. A cow which had thrown a cretinoid calf might produce a healthy one at a subsequent pregnancy. No enlargement of the thymus had been found.

At the same meeting a paper was read by Mr. G. E. Gask on a case resembling acute rheumatoid arthritis in a woman of twenty-nine years. The symptoms came on during the puerperum. A few days after labor the right knee became hot, red, and swollen. Other joints became affected, both knees, both ankles, both wrists, and the metacarpals were attacked. Salicyates gave no relief Bacteriological examination of the synovia from the knee joint revealed, both in films and cultures, an organism indistinguishable from streptococcus pyogenes. But injected into a mouse subcutaneously, and into a rabbit imtravenously, it proved non-virulent. Mr. Gask classed the case a rheumatoid arthritis, though some might be inclined to look upon it as a mild attack of rheumatic fever. Certainly we may recognize the existence of an acute stage of the rheumatoid affection, but it is hardly practicable to differentiate it unless the chronic lesions follow. The organism found, too, is not more characteristic than the clinical symptoms, and does not fulfil the conditions laid down by bacteriologists, inasmuch as it proved non-virulent to the animals into which it was injected. It appears to me, therefore, that it cannot be held for certain that the cause in this case was the microbe, though that is not improbable. Whether the organism found may be a variation, brought about by environment or other circumstances, is a question which opens the wider one of whether specific varieties may be evolved from a primitive streptococcus, a problem too intricate for me to enter on here. I may, however, recall the recent research of Drs. Poynton and Paine, who found in rheumatic fever a minute organism which is steptococcal in liquid media, but staphylococcal in arrangement on solids. This produced in rabbits lesions identical with those of the cases, and in these lesions of the animals they again found the organism. The virulence of this microbe was low and was not easily raised, but it appeared to be constant.

With regard to the relations between acute rheumatism and other rheumatic conditions, spa physicians, who see most of the chronic forms, are pretty well agreed that the differences were essential. This was emphasized at recent meetings of the Bacteriological Society, particularly with reference to the dietary suitable to each. Though the majority would restrict the diet in acute or subacute cases, they were for more nutriment in chronic cases. Dr. Luff expressed this view, especially with regard to rheumatoid arthritis, which, he said, is essentially a disease that requires good feeding—a diet as liberal as the digestion will allow. There was some regret expressed that English spa physicians did not find that patients who required restriction were as willing to submit at home as when they went to foreign resorts. Perhaps the real difficulty arises because the caterers in hotels and other establishments are reluctant to let the doctors control their menus.

Stirred up, apparently, by the statements of the anti-vivisectionists last week. several questions have been asked in the House of Commons. Further I hear that an action for libel is being brought against Mr. Stephen Coleridge.

A site of 150 acres has been selected for the King's Sanatorium. It is in a delightful part, not far from Haslemere.

The London University is likely to follow the example of Birmingham in granting degrees in dentistry. Then we may be sure the Northern universities will not be long behind.

In the course of their visit to Scotland, the King and Queen opened the new Edinburgh hospital for infectious diseases, which has cost £350,000. Accommodation is provided for 600 patients.

THE ADAPTABILITY OF WESTERN TEXAS CLIMATE FOR THE TREATMENT OF CONSUMPTIVES.

To the Editor of the Medical Record:

Sir: Desirous of adding my quota of experience to a cause which I consider more worthy of consideration than any other before the medical profession of our country to-day, namely, the proper caring for our American consumptives, and believing that my many years of observation upon the subject have borne some practical results, so far as benefiting these cases is concerned, I beg to recommend a climate which certainly will be beneficial to all who resort to it in the early stage of phthisis.

Without consuming space upon the climates of New Mexico, Arizona, and Colorado, the three most famous territories in America, and justly so, for the relief of consumptives, or upon other less favored localities, the writer simply desires to introduce his adopted State to the consideration of the medical profession of this country, with the sole object in view of pressing her claim for recognition as one of the most favored spots on earth for the sure and prompt eradication of phthisis pulmonalis, if such cases take advantage of her climate in the early stage of that disease.

Western Texas, that portion of the Great Lone Star State especially adapted for the cure of phthisis, and of which this letter is particularly descriptive, comprises all that territory situated between the Colorado river on the east, the Rio Grande on the west, the thirty-second parallel of north latitude on the north, and the Gulf of Mexico on the south. In extent it is larger than all England, and is easily capable of accommodating over 10,000,000 human inhabitants.

The surface of this country is mainly undulating, except along its southern boundary, which is level, and rises from an elevation of 500 feet in the east to one of 5,000 feet, or higher, along its western border. Within the limits of the country just described, it is safe to say, can be found the natural sanitarium of the world. The winters here are comparatively short and mild, while the summer heat rarely if ever attains a degree to be oppressive, while summer nights are always cool and delightful.

Three or four important lines of railroads traverse West Texas, so that most portions of the country can be easily reached by health-seekers, and along these lines the luxuries of life can nearly always be found; if proper effort is made to procure them. Moreover, an abundance of pure water can readily be obtained, as likewise an abundance of nutritious foods.

Cities, towns, and villages to the number of a hundred or more are interspersed all through this region, and the residents thereof are, in the main, quiet, peaceable, and intelligent. A few years ago nearly all of West Texas was

one vast cattle ranch, or, more correctly speaking, a continuous link of them; but to-day most of these pastures have been converted into beautiful farms, and the cowboy, with the Indian, has retreated before the school teacher and the industrious farmer.

The winters and summers of West Texas are comparatively mild, the degrees of heat and cold never attaining the extremes observed in many of those localities elsewhere resorted to by health-seekers, consequently invalids are thus enabled to be in the open air for a longer period of time than perhaps in any other State in the Union. A remarkable peculiarity of the atmosphere in West Texas is shown by the fact that, in the center of this health district in mid-summer, fresh meat suspended in the open air will remain there indefinitely without tainting; and incised wounds, under any sort of care, rarely even suppurate. In other words, the atmosphere here is inimicable to pyogenic germs, and in this property its anti-bacillary qualities no doubt reside. It has been asserted by authorities on phthisis that there is nothing specific in any atmosphere for this disease, but in the light of recently discovered facts this statement to the writer seems questionable. The climate of West Texas will restore to health 85 or 90 per cent. of all phthisical cases consigned to its care in their incipiency; and this too with so much certainty that climate in this instance could properly be styled specific.

Nor is its benefits confined to incipient cases alone, since hundreds of human beings to-day are enjoying excellent health in Western Texas, who were carried there upon their beds in search of health many years ago.

So large is the territory under consideration that a description of the various resorts to be found there would be out of the question in an article like this, therefore only brief mention can be made of some of them, except of one.

San Angelo, at the western terminus of the G. C. & S. Fé Railroad, and Llano on the Austin Branch of the Central are excellent and famous health resorts, situated respectively about 1,800 and 1,000 feet above tide water, and each quite accessible by rail.

Marfa and Ft. Davis are further west and very much higher, being 5,000 feet above the sea. These are along the line of the Southern Pacific Railroad, but are not so easily reached as the first two mentioned, by reason of their distance. Perhaps the best locality for consumption in all Texas, if not the best adapted place in the world for such cases, is at Comfort. This little German village of 600 inhabitants is situated in Kendall County, on the San Antonio & Aransas Pass Railroad, just fifty-two miles northwest of San Antonio. It is about 1,700 feet above sea level, and is surrounded by hills and mountains of considerable magnitude. Along the south side of the village runs the Guadalupe, a most beautiful stream of clear water, while the whole face of creation around is dotted with elegantly-kept farms, teeming with luxuriant verdure nearly all the year round.

The air here is pure, elevated, crisp, and dry, and for the most part of the year it is warm, thereby constituting an ideal lung food. This atmosphere is inimicable to putrefaction, and the bacilli of tuberculosis rapidly die out under its strong influence. Here one never feels fatigued, and therefore "that tired feeling," so often complained of by denizens of lower districts, is never heard of here.

Comfort being only fifty-two miles from San Antonio, and on a railroad, is quite easily reached from that city. There are some excellent physicians located here, and nearly any luxury desired can be obtained without delay. It is at Comfort, Tex., where Camp Reliance is located and where invalids, both male and female, reside in tents all the year round for the cure of their disease, relying on the "open air" method.

Probably the first questions suggested to the reader of this article would be: First, How can one reach Comfort? Second, What would the round trip cost? Third, How long should one remain in that climate before he could safely consider himself cured? Fourth, What accommodations are obtainable out there? Fifth, What vicissitudes would one have to undergo while remaining out in Texas?

These are all pertinent and practical questions, and experience shows that they are the usual inquiries made by prospective health-seekers to Texas physicians. The writer can only answer number one and two by basing the invalids out of San Antonio. As is well known, this last named city is the great mecca of the southwest for consumptives. Here they annually flock by the hundreds, and from San Antonio many of them scatter out in all directions in search of better places, as information directs them. There are four great lines of railway running into San Antonio, and all of them transport invalids to this section. These lines are the Southern Pacific, the San Antonio & Aransas Pass, the Missouri, Kansas & Texas, and the International & Great Northern railroads.

Take whichever route is most conveniently reached; though the S. A. & A. P. has established a route out of Chicago via the M. K. & T. road by which passengers can go through to San Antonio without change of train, a great advantage to the invalid traveler.

From San Antonio your trip, fifty-two miles, is over the S. & A. P. R.R., familiarly called the "S. A. P.," a beautiful and picturesque route, and the fare is $1.55 each way.

Second, at Comfort, or anywhere around in the neighborhood, good accommodations can be obtained in hotel, on ranch, or in tents, at from $25 to $30 a month, and your stay in this country should be from four to six months, according to the severity of your case, in order to secure permanent benefits therefrom. Thus in mild cases the round trip from San Antonio to Comfort and back should cost you not exceeding $200 for a six months' trip, including everything. As a matter of course, severer cases require a longer stay, while those bed-ridden who go should expect to remain there a year, or even longer.

Answering question five the writer will state that there are no vicissitudes in store for invalids who go to Comfort over and above occasional inconveniences common to all travelers. The climate there is very nearly perfect; the people (nearly all German) are quiet, honest, industrious, and sociable, and it is this very character of the people and quality of the atmosphere that make for Comfort the ideal place for invalids to go to.

There is also an abundance of nutritious food to be found in that country, such as milk, eggs, butter, fresh meats, and vegetables, while game and fish abound plentifully, nearby.

Finally, the invalid is in hailing distance of civilization, a most important point to be considered in treating these, cases, telephone and short railway connections being had with San Antonio, the largest city in the southwest, and the most attractive one in the State.

This proximity to so well a supplied base as San Antonio, with its luxuries and attractions, along with all the natural advantages just enumerated, make the little village of Comfort, in the opinion of the writer, ahead of any place in Texas, if, in fact, it is not the superior of any to be found in all this country as a resort for the proper accommodation and treatment of consumptive cases.

Since writing the above, it is learned that a station has been established at Camp Reliance, on the S. & A. P. R.R., just fifty miles from San Antonio, and that tourists are finding this an excellent resort to stop at. The writer would be pleased to give further information to any one who might desire such upon the climate and resorts of West Texas.

C. H. WILKINSON, M.D.

GALVESTON, TEX.

PROFESSIONAL SERVICES TO EACH OTHER.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The excellent editorial article under the above caption in the MEDICAL RECORD for May 16 is one that must appeal to very many of us. It is a question that I had to consider seriously and at length, and for some years have put my practice in the matter on grounds that are least comfortable, and some one may like to have the outline. I am not yet so busy that I need to charge physicians a fee for operative work or for consultations, for themselves and members of their immediate families. It is a pleasure to offer such services, and to say that their are no obligations, and that even a gift of any sort would make me feel uncomfortable. If I have to go out of town to work, it is my custom to make a regular charge of twenty dollars per hour for time, and to add the expenses of the trip, but to make no charge for services rendered. It is necessary to make the same charge to physicians as to laymen for time, in out-of-town work, in order to avoid actual loss.

In selecting a physician for medical work in my own family, it was stipulated that he was to charge his regular fees for visits. Madam often wants him to come in to see the children and other members of the family when there is no real necessity, but the effect of the visit is always worth more than it costs, and we are free to call him when we want him, without leaving the question of necessity to him at all.

M.

Researches on Hibbertia Volubilis.—J. Reid describes the chemical characteristics of the extracts from the fruit and pistils of this plant, which grows in New South Wales. Internally the preparations lower blood-pressure and dilate the pupil without any impairment of accommodation. They irritate the tongue and gullet, and probably possess aphrodisiac properties. Certain preparations cause slight nausea, salivation, and blackish stools. The author thinks the drug may have some value as a germicide.—*The Lancet.*

Progress of Medical Science.

Journal of the American Medical Association, May 30, 1903.

The Treatment of Empyema by Continuous Aspiration.—W. Van Hook gives the details of two cases. He advocates the plan of irrigation suggested by Perthes, which consists in making an adequate chest opening, resecting a rib if necessary, and then maintaining continuously a pressure less than that of the atmosphere in the pleural cavity, so that the lung may be made to approach more rapidly to the chest wall. A pump is used which is actuated by the running water of the hydrant. There must be constructed a proper cover for the wound; then there must be a continuously acting air pump to remove the air from the pleural cavity, and finally there must be a collecting vessel supplied with a manometer. The mode of construction of all these pieces of apparatus is detailed by the author, and his directions must be consulted by those interested. The entire outfit can be provided at a cost of only a few dollars. Van Hook quotes Perthes as saying that in all recent cases the lung becomes distended in a few days while the secretion diminished slowly and the healing of the space remaining after the removal of the drain occupied a considerable time. This is explained by the statement that a certain time is required for the death of the pneumococci and streptococci imbedded in the superficial layers of the pleura.

Acute Suppurative Cervical Adenitis of Infancy.—According to T. S. Southworth, this condition is generally referable to absorption of septic material from the nasopharynx, and generally occurs before the third year. Incision is to be small and along the natural lines of the neck, so as to leave as small and as imperceptible a scar as possible. Incision should be delayed until local pointing occurs, but not so long delayed as to allow of the skin becoming undermined. This recommendation also should in no wise be construed to apply to the deep brawny phlegmon of the neck occurring in the course of scarlet fever in which early incision is urgently indicated to prevent destruction of tissue if not of life. The conclusions to be drawn from the author's experience are: (1) The abortive of acute cervical adenitis of infancy is most promising, especially in children over one year of age. (2) The younger the infant, the greater is the liability to suppuration. (3) A continuation of high temperature makes the occurrence of suppuration probable.

Unilateral Disease of the Kidney Simulating Stone.—J. Ransohoff says that the pain of stone may be simulated by any gross pathological condition of the kidney or ureter, such as tuberculosis, tumor, hydronephrosis, etc., and also by microscopic changes in the kidney affecting either the secreting or circulatory structures or the supporting framework and capsule of the organ. While ordinarily renal colic is associated with intrarenal retention from obstructed outflow, in certain chronic affections of the kidney with acute exacerbations the distension of a resisting capsule from within may be the cause of a typical renal colic. The author asserts (and describes a case to illustrate his statement) that chronic nephritis often manifests itself as a unilateral disease, and that, just as tuberculosis or infarct, though homogenetic, may be unilateral, chronic interstitial, parenchymatous, and capsular inflammation of the kidney may be limited to one side.

New York Medical Journal, May 30, 1903.

A Supposed Sarcoma of the Kidney Cured by the X-ray Treatment.—The patient of C. H. Richmond was a woman of forty years who suffered from a tumor of the right side, which, from its exact location and rapid growth, was regarded as a sarcoma of the kidney. At the time the *x*-ray treatment was begun the patient's pulse was ranging from 108 to 120, the evening temperature from 101° F. to 102° F.; she had night sweats, had ceased to menstruate, had lost about twenty pounds in weight, was not able to dress herself without help, and measured two inches and a half, or three inches more than normal in circumference just below the ensiform cartilage, with the tumor extending downward as far as the crest of the ilium. Daily treatments were given for fifteen minutes each for a period of nineteen days. At the end of this time the temperature was nearly normal—on some days entirely normal—night sweats had lessened, the tumor had apparently ceased to grow and seemed softer, her appetite was good, she slept well, the pulse had somewhat improved, and she was buoyant in spirits. She was then removed to a hospital, the ray treatment being there continued. Nine weeks later the growth had entirely disappeared, so far as could be determined by bimanual palpation.

Clinical Observations on Backache.—R. W. Lovett divides the causes of bachache into too main classes: (1) those due to spinal causes and (2) those due to causes existing outside of the spine. Of the first class we may have static causes as existing in the spine (faulty spinal attitude and pain from lateral deviation of the spine) and causes in the spine of a traumatic or inflammatory nature (sprains of the back, cases without obvious causes, Pott's disease and arthritis deformans). Causes outside the spine include real flat foot, pronated foot, and contracted foot This latter condition is characterized by a shortness of the muscles at the back of the calf. If the patient sits in a chair and the leg is held horizontally with the knee straight, the foot cannot be flexed beyond a right angle and often not to a right angle. The condition may be inherited or be associated with a mild rheumatism or neurasthenia. The pain is generally in the small of the back, and is aggravated by standing or stooping forward, although it also results from walking. Treatment calls for the support of the arch of the foot and the stretching of the calf muscles.

The Eye in Its Relation to General Disease.—N. D. McDowell enumerates the various eye disorders found in the common general affections in connection with gonorrhœal ophthalmia, he mentions the case of a physician suffering from the malady, infection having been derived from a baby for whom the physician was caring. Treatment was as follows: Within a few hours from the onset of symptoms the physician was put to bed, cocaine instilled, and every part of the conjunctiva of the infected eye pulled down with forceps and bleached with nitrate-of-silver solution, 20 per cent. Ice cold pledgets of cotton were kept on the eye all night. The next morning the conjunctiva was again thoroughly bleached with nitrate-of-silver solution of 10 per cent. strength, and ice applications were continued half the time. The secretions of the eye were examined daily after this and no gonococci found. In four days the patient was well.

The Essentials for Aseptic Labor.—General directions are given by A. E. Gallant, who thus enumerates the articles the accoucher should carry to the patient: (1) Drugs, whiskey, chloroform, acetic acid, silver nitrate solution, 2 per cent. tincture of green soap, hypodermic tablets, fluid extract ergot and washing soda. (2) Instruments forceps, artery forceps, vaginal dressing forceps, needles and holder, scissors, tenacula, Chamberlain tube, nail file, vaginal speculum. (3) Sterile supplies, operating gown, cotton-ball sponges, sterile gauze, six sterile towels, rubber gloves, two nail brushes, rubber catheter, silkworm gut and tape for cord. Concerning clean hands, his advice is to lay stress on thorough scrubbing rather than the routine use of any special antiseptic. They should be scrubbed in hot running water until all the soap used has been removed.

Medical News, May 30, 1903.

The Cure of Anal Fissure without Operation.—S. Lewis describes his treatment as consisting in the application to the fissure and surrounding area of a saturated solution of potassium permanganate and the use of a suppository containing sulphichthyolate of bismuth. Technique is important. The patient is placed in semi-prone position on the table, supporting her own right buttock. On separating the folds at the mucocutaneous junction, as a rule, the outer extremity of the fissure or painful ulcer, or at least a red streak indicating its location, can be seen. It may be hidden behind a pile and may be multiple. Cocainization is often required before satisfactory examination can be made, and may have to be repeated on reaching the fissure. In case of spasm, rarely a large flexible bougie may be passed and left *in situ* five minutes. The fissure is exposed, gently cleansed with warm water, and permanganate applied on a tiny swab. This should extend over the whole surrounding area. Smarting lasts from two to ten minutes. The writer employs a suppository, sold under the name of anusol. In most cases it can be inserted by the patient. It should be employed night and morning. The usual dietetic and medicinal treatment of constipation is prescribed, and the patient told to report in two days. The worst cases are confined to bed. At the second treatment the operation is repeated, only the cocaine is omitted. At the third, suppositories may be reduced to one daily, at bed-time. If this treatment fail to give immediate relief, there are probably other fissured areas present. These should be found and treated.

A Report upon the Physics and Therapeutic Value of Cathode and Ultra-violet Rays.—Roswell Park concludes from the results of extensive experience that: (1) Cathode and ultra-violet rays afford methods of treatment for extremely new growths of limited area and superficial character, which, while not exactly certain, are extremely promising. (2) They not only cause no pain, but tend to relieve pain, both superficial and deep, in a most pleasing and satisfactory way. (3) They are adapted to cases which can hardly be submitted to any other method of treatment, and they afford more hope in delayed or inoperable cases than does any other method of treatment.

(4) It will be found that the odor of putrefaction may often be suppressed by their use and the putrefactive process itself checked. (5) Burns and intense dermatitis, so frequently noted when the treatment first came into vogue, may now be almost certainly avoided. (6) More than this they afford a supplementary method of treatment after operation, by which the benefits of the same may be enhanced and enlarged. (7) It is not necessary to intermit such work as the patient may be engaged in, in order to carry out the *x*-ray or phototherapeutic method of treatment.

Philadelphia Medical Journal, May 30, 1903.

Uterine Fibroma Near the Menopause.—George Eretv Shoemaker says that among the medical heresies which are fast fading away is the idea, once popular, that fibromata of the uterus are likely either to diminish in size or to cease to be and to grow about the time of the menopause. This idea appears to have had its origin in the inability of surgeons safely to remove such tumors, and in their effort to give to the patient the only hope in their power. An experience of many years in gynecological dispensaries, and of eleven years as gynecologist for city hospitals, has failed to bring to the notice of the writer a single case which has bad such a termination. He has, however, operated upon many who have been deluded with this hope up to the age of fifty to fifty-five years, finally coming to operation on account of the severe and increasing hemorrhage, growth of tumor, recurrent attacks of peritonitis or salpingitis, while by the degeneration of heart or kidneys and other indirect consequences of anæmia, the patient's vitality has been forever impaired. The writer then quotes three such cases. The danger from operation in cases of this class while greater than in the simpler forms of abdominal sections, is not very great, and the mortality should not exceed 6 per cent., which is largely made up by complications, such as pyosalpinx, recurrent peritonitis, or the effects of hemorrhage, all due to delay.

Preliminary Report of an Operation for Abdominal Pregnancy of Twenty-one Months' Duration.—Charles P. Noble presents this report. The patient was a nullipara of thirty years. The illness in question dated from early March, 1901, when she missed a period. Two weeks later she was taken with a sudded pain at one in the morning. The pain was sharp, severe, and lancinating, and located in the right iliac quadrant. For six months her condition was that of a normal pregnancy. The last of August she had an attack of dull, dragging pain in the lower part of the abdomen, vomiting, chills and fever. At the end of four weeks the patient improved, the breasts and abdomen became smaller, and the uterine bleeding took on more the character of menstruation. The abdominal mass persisted and a diagnosis of fibroid was made. Vaginal examination discovered a hard mass having the characteristics of a fetal head. The uterus was pushed to the right. On November 26 the abdomen was freely opened and the fœtus extracted. The writer believes that the ruptured tubal pregnancy occupied the space behind the left broad ligament, and that this space was roofed in by adhesions between the upper border of the broad ligament, the sigmoid, and omentum. The fœtus was in an excellent state of preservation.

American Medicine, May 30, 1903.

The Forcible Reposition of Congenital Luxation of the Hip.—Gwilym G. Davis declares that the attempts at forcible reposition of congenitally luxated hips have given rise to so many accidental traumatisms that the question has arisen as to whether it is not appropriate to advocate more conservative measures. He offers the following suggestions: That the tendons of the adductor muscles at least be cut subcutaneously, and thus considerable traumatism and mauling of the soft tissues at this point be avoided. Violent stretching movements in all directions as a routine practice to loosen up the joint are unnecessary. It is a serious question if they do not increase the functional disability and favor the tendency to displacement. Violent tractions for immediate replacement should be totally abandoned. Forcible traction is the agent mainly responsible for the traumatisms which are inflicted. The thigh should be flexed on the abdomen, followed by downward pressure on the knee with abduction, external rotation, and gradual extension. Pressure is made on the trochanter posteriorly, while the limb is carefully extended. Abduction is afterward maintained to an extent sufficient to prevent the head from escaping from its new position. If the adductor muscles prevent the desired abduction they can be tenotomized. To make pressure on the trochanter it can be done with the hand beneath or rested either on a hand roll, the edge of the table, or Kŏnig's block. If serious difficulty is met in attempting reduction, then, instead of increasing force, it is better to confine the patient to bed with the limb abducted and with weight extension, if desired, for two to eight weeks or even longer, and then again attempt reduction. Rather than resort to the great force now at times employed, the writer thinks it better to incise and clear a way for the head of the bone.

Streptococcus Infections.—Leonard K. Hirschberg states that of the eighteen species of streptococci pathologic for man, there are only two divisions morphologically, cocci which occur unpaired in chains, and diplococci, occurring also in chains. Streptococci are isolated in pure culture from all uncomplicated cases of erysipelas. According to Holt, "croupous tonsilitis is nearly always due to the streptococcus." The most malignant and frequent cause of child-bed fever is undoubtedly the streptococcus. Streptococci are often obtained in pure culture from traumatic cases of cerebrospinal meningitis. They are, according to Baginsky, the cause of scarlet fever. These organisms have been found circulating in the blood of chorea patients. There is little warrant at present for dividing the streptococcus into eighteen or more species. From the multiplicity of pathologic processes concerned, in which the streptococcus is undoubtedly found always, it is quite likely there are distinct species, or at least varieties of streptococci involved, but our present means of separating them proves it is open to considerable doubt.

Etiology and Treatment of Retrodeviations of the Uterus.—Charles A. Robertson says that the chief single cause of retrodeviation of the uterus is rupture of the perineum involving the lavator ani muscle and its fascia, together with a heavy uterus. The most important prophylactic measure in forestalling this condition is the proper care of the parturient and puerperal woman. The indication to be fulfilled by surgical treatment is to replace the uterus to as near its normal state of anteversion as possible and fix it there with a minimum amount of subsequent physiologic disturbance. No operative procedure designed to cure retrodeviations of the uterus is complete without the proper application of the principles of plastic surgery to the restoration of the function of the pelvic floor. There is perhaps no department of surgery which requires more skill and judgment in the diagnosis and selection of cases for a particular operation than the one under consideration.

The Lancet, May 23, 1903.

A Case of Arterial Occlusion and Gangrene.—The patient of A. Dunlop was a retired army officer of fifty-three years who had suffered for some time with pains in the foot suggestive of gout and at other times presenting the local syncopal and asphyxial conditions seen in Raynaud's disease. In course of time evidences of gangrene appeared in two of the toes, together with occasionally symptoms suggestive of septic poisoning. The affected parts were removed with temporary benefit. Finally a good share of the foot became gangrenous, and was removed by section through the fourth metatarsal bone and disarticulation of the fifth at the tarsal end. Some months later obstruction appeared in the right femoral vein. There was pain in the groin the stump of the foot became swollen and purple, and there were paroxysms of severe pain in it. The whole leg was œdematous and the protruding bone in the stump became inflamed and bare. A fortnight later a similar attack took place on the left side, and it was over a month before both legs had recovered, and even then there were frequent pain and great tenderness in the stump of the right foot. In spite of the fact that the condition of the arteries could not be positively learned, and though perhaps the possibility of slow-forming thrombus in atheromatous or sclerosed vessels could not be wholly excluded, the author was inclined to regard the case as one of Friedländer's arteritis obliterans.

Abdominal Pain as a Symptom in Acute Lobar Pneumonia.—J. R. Smith refers to a series of cases recently under observation, in every one of which the initial symptoms of the disease included abdominal pain. In each case the signs and symptoms were typical of acute lobar-pneumonia. In two instances the pain was so severe as to call for the hypodermic use of morphine.

British Medical Journal, May 23, 1903.

Traumatism as a Factor in the Etiology of Pulmonary Tuberculosis.—James Weir relates the history of a case in which a patient gave an account of an injury received a month previously by receiving a blow with a heavy pair of tongs. The tongs had struck him on the right side, over the base of the lung, in the mid-axillary line. Tuberculosis developed. It is possible, of course, that tubercle may have developed as a sequel to a traumatic hemorrhage from contusion of the lung at the seat of injury which would thus furnish a suitable soil for the growth of the

nvading bacilli. But the fact that there was no cough nd no hæmoptysis for some considerable time after the nfliction of the injury, leads the writer to suppose that the uberculous infection was in reality superimposed upon he deflated area of lung tissue, consequent upon trauatic pleurisy. This patient contrived by means of cod-iver oil and pulmonary antiseptics, reinforced by breathing xercises, not only to place something to the credit of his ody weight, but to free himself, as far as physical and nicroscopical examination could ascertain, from an attack f pulmonary tuberculosis. Pulmonary physical culture eems to the writer to be the one method whereby this nchoring and consequent devitalizing of the pulmonary issues by pleuritic adhesions may be rendered comaratively impotent.

Remarks on the Influence of Wind on Phthisis.—W. Gordon concludes: (1) West and southwest winds in Devonshire have a marked influence on phthisis, raising he phthisis death rate amongst populations exposed to hem and injuring those who have already developed the isease. (2) This bad influence is probably due to the act that west and southwest winds are the prevalent trong wet winds of the county. (3) It is reasonable to elieve that strong, wet winds anywhere may produce imilar effects. (4) The bad effects may be possibly xplained by the chilling and depressing nature of the inds, and by their tendency to excite bronchial catarrh n those exposed to them.

Deutsche medicinische Wochenschrift, May 7, 1903.

Acute Primary Osteomyelitis of the Spine.—F. Weber eports an interesting case. The patient was a male, ifteen years of age. His father had died of tuberculosis, otherwise the personal and family history was excellent. The attack began suddenly with pains in the back and enderness over the spine from the tenth dorsal vertebra o the coccix. These symptoms rapidly increased in everity, and were accompanied by fever and the concomtant appearances. Soon the involved region became nuch swollen and œdematous, and the pain began to adiate over the abdomen and down the thighs. The notility of the upper and lower extremities remained perect and there were no pupil or cerebral symptoms. The atella reflex was increased. The general condition beoming worse on the tenth day, the operation was performed. The swollen region was opened throughout its ntire extent and a large amount of pus evacuated. Upon xamination it was seen that the lumbar vertebræ were nvolved. The diseased bone was removed so far as ossible and the wound drained. The pus showed the taphylococcus pyogenes aureus in pure culture. Immeliately following the operation the temperature fell and he general condition markedly improved. This con· inued for two weeks when a second rise of temperature ccurred. Examination showed a beginning abscess in he gluteal region. In due time this was opened and rained. Here, also, the pus showed a pure culture of the taphylococcus. Both of the wounds pursued a favorable ourse, and in twelve weeks the patient was discharged ured.

Volumetric Estimation of Albumin in the Urine.—Oskar Rössler gives a modification of his original method, which hows very slight variations in the quantity of albumin resent in a given specimen of urine, and by the means of vhich the daily variations in the amount of albumin may e accurately estimated. Five c.c. of dilute acetic acid are laced in a test tube and two or three drops of the following olution added: succinic acid 2 g., hydrarg. biehlor. 1 g., odium chloride .1 g., distilled water 50 c.c. The carefully filtered urine is then pipetted down the side of the ube until it forms a layer upon the top of this mixture. The presence of albumin is denoted by the formation of a vhite band in the urine at the junction of the two liquids. nd the amount of albumin is directly proportionate to the epth of this band By using test tubes of the same size nd like quantities of the urine and reagents employed, an ccurate estimation of the variation in the amount of lbumin in different specimens of urine may be obtained. The method is to be recommended because of its simlicity. By it the albumin due to nephritis may be ifferentiated from that arising from other causes, since he amount of the former is influenced by rest, exercise, athing, etc., while, in the latter, the quantity remains tationary, or nearly so, under these conditions.

Berliner klinische Wochenschrift, May 11, 1903.

High Enema in the Treatment of Chronic Catarrh of the Large Intestine.—Ludwig v. Aldor strongly advises this nethod of treatment as the result of extended experience n all classes of cases of this disease. It is well known that he usual forms of medication are of but little avail. and hat dietary measures usually also give unsatisfactory reults. Experience has shown that fair results are obtained in many cases by the so-called Carlsbad "drink-cures," and the method of treatment grows out of this experience. By the use of high enemas the Carlsbad water is thus brought in large quantity into direct contact with the diseased tissues. The enemas should be given once every twenty-four hours and consist of from 1 to 3 liters—the smaller amount being used at first and the quantity gradually increased. Before using the enema the lower part of the large intestine should be thoroughly washed out with sterile water. In using the enema, a tube at least 85 cm. in length should be employed, and this should be introduced for its entire length. The temperature of the water should be at least 45° C. For several hours after the enema warmth should be applied to the abdomen and the patient kept in bed. By following this method the author has employed the enemas in several hundred cases with excellent results and no ill consequences. The enemas are usually retained from three-quarters to two hours.

Freezing-point Estimations of Nephritic Urine.—H. Roeder says that in nephritis the absence of the marked normal lowering of the freezing-point of the urine during the ingestion of large amounts of liquids is to be regarded as a sign of the lessened ability of the kidney to accommodate itself to conditions arising from the introduction into the body of large amounts of liquids. Extended observation has also shown that the freezing-point of the urine is influenced quite markedly by the diet, so that the results obtained by Karangi, Lindemann, and others can only be applied to those cases which are upon a regulated nephritic diet.

Münchener medicinische Wochenschrift, May 12, 1903.

Tuberculin in the Diagnosis of Phthisis.—Freymouth praises this method of diagnosis and reports his experience with 170 cases. Only that preparation of Koch's known as "old tuberculin" should be used, because it most regularly gives a satisfactory reaction and absolutely no danger from infection attends its employment. No patient whose evening temperature exceeds 37.1°-37.2° C. should be submitted to this test. The initial dose must be small—from .1 to 1 mg. If no reaction is produced on the following day the dose may be doubled, but if the reaction is slight (temperature elevated $\frac{1}{4}$° to $\frac{1}{2}$°) only the initial dose should be repeated. In cases which fail to give any reaction to these small doses the amount used may be gradually increased to 5 to 10 mg., but this quantity should never be exceeded. The smaller the dose used the more specific is the reaction. The type of reaction varies; as a rule in pure cases the fever appears within a few hours after the inoculation, quickly reaches its height, and as quickly subsides, so that the whole reaction occupies but about twenty-four hours. Occasionally there is a preliminary slight elevation followed by a fall and then a marked rise. Delayed reactions almost always occur in complicated cases, and are to be regarded as characteristic of such. The inoculations should always be intermuscular and never subcutaneous. All tuberculin injections are liable to be followed by local disturbances, but the intermuscular the least so. Taken in all, there can be no question but that when properly applied the tuberculin test is the most valuable method for the diagnosis of tuberculosis yet devised.

The Explanation of the Favorable Influence of Bed-rest upon Phthisical Fever.—Pickert thinks that this is mainly due to the venous congestion of the lower extremities, which is produced by the continuous horizontal position. As the result a large amount of the blood is kept out of the lungs and the tuberculous lesions become less active, the bodily temperature falling. Observations upon four phthisical patients show that uniformly the lowest temperatures were obtained while in the horizontal position. Slight elevations occurred when the patients were propped up in bed, but the lower extremities kept horizontal. The highest elevations were always present when the patients were allowed to be up and walking around.

French and Italian Journals.

A Singular Case of Saturnism in an Infant.—Giovanni Berti reports the case of a child of about two years of age which had suffered much from scurf skin. The mother neglected the child for months, but finally called in a physician, who prescribed Hebra's ointment. With a zeal equal to her former neglect, the mother persevered in the treatment, and ignoring all directions given, applied the ointment twice a day to the patient's head, then covering it with cotton batting. The scurf was almost cured by these proceedings, but alarming symptoms began to develop in the child, and after another long period of neglect, it was finally brought in consultation to the author. The symptoms found were very evidently those of lead poisoning, although colic, and the buccal sign of Burton and of Gubler were absent. Lead was found in the urine. Suspension of the ointment, and the administra-

tion of iodides succeeded in bringing about perfect recovery, to the surprise of the physicians, as the child's condition had been extremely serious.—*Rivista di Clinica Pediatrica*, May, 1903.

Etiology of Epidemic Dysentery.—Vaillard and Dopter have studied an epidemic of dysentery which occurred among soldiers at Vincennes in the year 1902. They found the same bacillus described by Chantemesse and Widal, Shiga, and since then by many other workers. With pure cultures of this microbe inoculated in animals the physicians have been able to reproduce a malady altogether like, in symptoms and in pathological anatomy, the spontaneous human dysentery. These physicians close their work with the following conclusion: The bacillus discovered and described in 1888 by Chantemesse and Widal, differentiated finally by Shiga, must be considered as the specific cause of epidemic dysentery in temperate regions and of a dysentery of the same nature existing also in hot countries. This determination, aside from its etiological and prophylactic interest, should lead to ideas of another kind, since the blood of immunized animals possesses certain preventive characteristics, and it can be legitimately prophesied that it will be efficacious in the cure of dysentery.—*Le Bulletin Médical*, May 13, 1903.

A Case of Eosinophilia in a Nursing Infant Whose Mother Was Affected with a Tænia Mediocanellata.—Enrico Gagnoni reports a case which he considers of interest because of the support which it gives to the theory that the tænia secretes some substance or substances as yet unknown, which enter into the circulation and occasion many of the symptoms of helminthiasis. A second interesting point is that the eosinophilia is in direct dependence upon the toxic substance produced, which, according to Ehrlich, might, in this case, act by stimulating the formative centers of the eosinophilic cells, in the bone marrow, or by exercising some special influence on these cells whereby they are called into the circulation. The author does not claim that his own case is in any way decisive, but considers it suggestive, and thinks that if more cases were noted, the occurrence of eosinphilia in a nursing infant might point to the proper diagnosis in the case of the mother.—*Rivista di Clinica Pediatrica*, May, 1903.

Cytodiagnosis of Cancerous Pleurisies.—Nattan-Larrier presents preparations designed to show that cytodiagnosis of pleural effusion may be, perchance, very useful in a case of cancerous pleurisy. In one observation, cytodiagnosis disclosed large elements of vacuolated protoplasm with multiple nuclei. In another case of pleurisy secondary to cancer of the breast, cytoscopic examination revealed the true cellular masses floating in the liquid. Two other observations with cytodiagnosis equally positive were as follows: one with a pleurisy consecutive to cancer of the stomach, the other to primitive cancer of the pleura or the lungs. The result of these examinations is that the large cell of vacuolated protoplasm is an element of diagnosis very important in cancerous pleurisy.—*La Presse Médicale*, May 13, 1903.

Tetanic Form of Cancer of the Pylorus.—Gouget reports this case. The patient was a man of forty-nine years, afflicted with stenosis of the pylorus. The tetany was characterized by a permanent contraction of the neck and trunk; constant apyrexia, the absence of headache, of all psychical trouble, Kernig's sign, and the constancy of the clinical picture excluded the diagnosis of cerebrospinal meningitis, whether tuberculous or not. Apyrexia, the absence of trismus, and of painful paroxysmal contractions did not allow the diagnosis of tetanus. Strychnine poisoning, uræma, and rheumatism could equally be excluded. Tetany remained. There exists a permanent form of tetany (four cases out of seventy-three observed by Escherich).—*Journal des Praticiens*, May 16, 1903

Tuberculosis of the Buttock Consecutive to an Injection of Tuberculin.—Tuffier had a patient who had, at the level of the great trochanter, two suppurating fistulas; the pus of which contained Koch's bacillus. The coxofemoral articulation, the ischium, and the femur were intact. The fistulas resulted from the opening of an abscess which was slowly formed after two injections of tuberculin, which had been given more than six years before. This abscess incised for the first time four years before, reformed and opened spontaneously two years after. The general condition of the patient was otherwise good.—*La Presse Médicale* May 13, 1903.

Concerning the Rôle of Intracellular Catalytic Processes in the Pathogenesis of Malignant Neoplasms.—John C. Hemmeter has made observations on his investigations concerning adenocarcinoma of the stomach. He concludes from experiments on tumor transplantation that gastric ulcers can be experimentally produced, and that the edges of these gastric ulcers can be brought to undergo adenomatous transformation by the injection of a cell-free and sterile fluid obtained from a cancer of the same organ from the same species of animal. Inasmuch as this filtrate was destroyed after being heated to 60° C., it was concluded that the agent active in causing this abnormal proliferation at the edges of experimental gastric ulcers was a calytic agent. These experiments extended through years. The writer considers how the cell builds put protoplasm. It is suggested that this is effected by means of intracellular catalyzers. The cell is conceived to be made up of innumerable ultra-microscopic compartments, and the more subtle and partial damage of cytoplasm and nucleus in disordering the orderly and normal performances of intracellular catalysis are set forth here. The writer concludes with a paragraph on metastases.—*The American Journal of the Medical Sciences*, April, 1903.

Book Reviews.

Obstetrics: A Textbook for the Use of Students and Practitioners. By J. Whitridge Williams, Professor of Obstetrics, Johns Hopkins University; Obstetrician-in-Chief to the Johns Hopkins Hospital; Gynecologist to the Union Protestant Infirmary, Baltimore, Md. New York and London: D. Appleton & Company, 1903.

The past few years have seen obstetric literature augmented by a number of excellent textbooks, each possessing peculiar merits of its own, and all far surpassing the older works in fulness of information and helpfulness to the student and practitioner. The present book is no exception in this respect, for, while necessarily traversing the same ground as its immediate predecessors, it is stamped with a pleasing individuality. Those who are familiar with the author's well-known views concerning the avoidance of vaginal examinations will not be disappointed with the clear and emphatic teaching on this point, but they will hardly be prepared for the statement that he does not make vaginal examinations in over 50 per cent. of his cases until about to discharge the patient. Even those who restrict themselves to very few such examinations during labor are often tempted to introduce the finger in the latter part of the second stage in order to keep themselves fully informed as to the progress of the labor, but our author insists that this is wholly unnecessary, and that the same object can be accomplished by pressing the fingers against the perineum to one side of the anus.

That very important, but ordinarily very dry part of obstetrics to the student, the mechanism of labor, is very clearly expounded in accordance with modern views. Even those who have always practised with satisfaction Credé's original method of expelling the placenta will do well to read what is said about the management of the third stage of labor, and the tyro in obstetrics should imprint upon his mind the statement, that manual removal of the placenta is more dangerous than forceps or version. The treatment of the important subject of the application and use of the forceps is sound and judicious, yet many will think the author a trifle too dogmatic when he expresses the opinion that it is *never* necessary to apply the forceps to the after-coming head because Mauriceau's method of extraction is all-sufficient. Symphyseotomy is characterized as a very serious operation, and one requiring more exact diagnosis and a longer convalescence than Cæsarean section, while the maternal mortality is equal to that of the latter operation, and the fetal mortality is considerably greater. The chapter on pelvimetry and the management of labor in contracted pelves is worthy of special commendation.

On the whole this is a work of which the talented and scientific obstetrician of the Johns Hopkins Hospital may justly feel proud. It is a book which the student and young practitioner may use as their guiding star, for it is sound in its teaching, comprehensive in its scope, and supplies an excellent bibliography for those who thirst after greater knowledge.

Surgical Anatomy, A Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By John B. Deaver, M.D., Surgeon-in-Chief of the German Hospital, Philadelphia. In three volumes. Vol. III. Philadelphia: P. Blakiston's Son & Co., 1903. 4to, pp. 816.

Volume III, which completes the work, treats of the abdomen, pelvic cavity, lymphatics of the abdomen and pelvis, thorax and lower extremity, and is illustrated by 177 superb full-page plates. With the two former volumes the illustrations number nearly 500, from original drawings of dissections. The present work fully sustains the reputation of its predecessors, and is in every respect a

classic of its kind. The author combines the anatomist and surgeon in a thoroughly practical way, and from both aspects reconciles surgical technique with topographical and anatomical conditions. His discussion of the abdominal cavity, which is the field of such varied and progressive operative work, is especially worthy of commendation. The complex relations of the different viscera are admirably depicted from actual dissections, and the reader has the cadaver before him in all the realistic demonstration of an actual dissection. Schematic drawings are occasionally introduced to bring out salient points of relationship, which are of value as leading landmarks for surgical procedure, but these are comparatively few in number for very obvious reasons. The anatomy of the appendix is very clearly presented, and the reasons for the choice of different incisions are quite satisfactorily shown. Altogether the work is one that will supply the place of a most comprehensive guide to every surgeon who may wish to perfect his methods on the basis of the broadest possible knowledge of all possible anatomical conditions. While it is true that the volumes are of a somewhat bulky character, they could hardly be otherwise to fulfil their purpose. It is safe to say that in its particular field the work is destined to become a leading authority.

A System of Physiologic Therapeutics. Edited by Solomon Solis Cohen, A.M., M.D., Senior Assistant Professor of Clinical Medicine, Jefferson Medical College. Vol. V. Prophylaxis—Personal Hygiene—Civic Hygiene—Care of Sick. Philadelphia: P. Blakiston's Son & Co., 1903.

The fifth volume of the series of Physiologic Therapeutics fully sustains the reputation of the preceding ones in the wealth of practical material it contains and the comprehensive treatment of the subjects selected. Most of the works on hygiene aim to minister to the needs of the general reader by giving him general principles for commonplace adaptation rather than to supply the real needs of the scientific student. The present work is distinctively excellent in making a departure from set methods and explaining the reason from advanced scientific standpoints. The various authors who have contributed special articles have succeeded in a very satisfactory manner in condensing and clarifying much that heretofore has been obscure and unintelligible. For instance, the theory of immunity is studied in all its bearings with a clearness of perception that proves the purpose of its presentation. Even Erlich's lateral-chain theory, with all its modifying complexities and multiplication of terms, is made reasonably comprehensive, and within the grasp of most readers. The bacteriologic factors of disease are so numerous and distributive that too much attention cannot be given to them in a treatise of this sort. In such respect the demand for accurate and up-to-date knowledge of the subject is very satisfactorily met. The toxins and antitoxins are discussed from the practical side of disease prevention, and their relations to each other are explained in a way that leaves nothing to be desired in bringing our present knowledge to the level of the most advanced news of the general subject. The chapter on the prevention of the transmission of disease by animals gives a most interesting and instructive account of the relation of the mosquito to malaria and yellow fever, with most admirable illustrations of the development of the infecting plasmodium. Very valuable facts are also given regarding flies as disseminators of infection.

The different infections of special organs and apparatus are exhaustively discussed in special chapters with such practical application of scientific disease prevention as must needs commend themselves to the most careful study of the general practitioner. The views on soil pollution and water supply are of especial value and importance in correcting and modifying many of the widespread and erroneous opinion on these subjects, even among well-informed medical men. In the necessarily limited space of this notice it would be impossible to refer in detail to many other excellent features of this admirable and exhaustive work; suffice it to say, however, that it is destined to take a first rank in its class and become a most valuable means of reference for the progressive practitioner. In its variety and scope it is almost encyclopædic.

Physical Chemistry for Physicians and Biologists. By Dr. Ernst Cohen, Professor of General and Inorganic Chemistry in the University of Utrecht; authorized translation from the German, by Martin H. Fischer, M.D., Instructor of Physiology in the University of California. New York: Henry Holt & Company, 1903.

This book contains a series of lectures constituting a résumé of those subjects in physical or general chemistry which are of importance in medicine. As many observations in medical literature are based on our newer conceptions of physical chemistry, the physician must become acquainted with these theories and methods, and the book is intended as an introduction to larger works now available. The subjects discussed are: reaction velocity, the inversion of cane sugar and catalysis in general, the action of ferments, the influence of temperature upon reaction velocity, equilibrium, the friction of liquids, osmotic pressure, the molecular weight of dissolved substances, the theory of electrolytic dissociation, electromotive force, and applications of these principles in the fields of hygiene, pharmacology, and physiology. Everywhere the relation of mathematical formulæ to the subject is brought out, though in a simple form, and altogether the work is an excellent one of its kind.

Mechanical Vibratory Stimulation, Its Theory and Application in the Treatment of Disease. By Maurice F. Pilgrim, M.D., First Vice-President of the American Electro-Therapeutic Association, Professor of Psychiatry in The New York School of Physical Therapeutics; Editor of the Department of Psychiatry in the *Journal of Advanced Therapeutics*. New York: Metropolitan Publishing Company, 1903.

The author outlines in an entirely conservative way what may be reasonably expected from the application of mechanical vibration in therapeutics. His aim is to state the principles and illustrate their practical application so as to make the presentation of the subject available and effective for the busy practitioner. For the author the vibratory treatment is not a "cure all," or an exclusive method, but merely one legitimate method. That treatment can, he claims, increase blood and lymph flow and nutrition; improve respiration, muscular and general metabolism, and excretion and elimination; soften and relieve contractures, engorgement, and congestion; facilitate the removal of tumors and exudates; and relieve pain; not uniformly or invariably, but with fewer disappointments than other physical therapeutic agents. The *modus operandi* is, in general, reflex action. The physiology of the organs is passed in review and plates and diagrams are given to elucidate the text. A chapter of directions is provided for the regional application of vibration for the chief diseases to which it is applicable. Altogether, this little work serves as a good introduction to the subject.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Professor Carl von Noorden, Senior Physician to the City Hospital in Frankfurt-a-M. Authorized American edition, translated under the direction of Boardman Reed, M.D., Professor of Diseases of the Gastrointestinal Tract, Hygiene and Climatology, Department of Medicine, Temple College, Philadelphia. Part I: Obesity, the Indications for Reduction Cures. Part II: Nephritis. New York: E. B. Treat & Company, 1903.

Part I of this work contains a sensible, straightforward discussion of the subject under the headings of simple obesity in otherwise healthy subjects, comprising advanced, medium, and slight degrees of obesity; and of complications with other diseases. The indications for interference and, equally, for non-interference are clearly laid down, and the dangers under certain conditions are alluded to. Considering the amount of misinformation, not to mention the plenitude of quackery to which the subject has given rise, Professor von Noorden's book is an addition to its rational literature.

In Part II the author gives the result of clinical and experimental investigations made by himself, or by his students, since 1885. The work is preëminently original, and is in the nature of an attempt to place the dietary in nephritis upon a basis of fact instead of upon that of the vague, traditional notions which are usually said to be "derived from the writer's forty years' experience," or some equivalent substitute for precise, detailed, statistical data, showing the actual results obtained in a series of thoroughly studied cases. For example, the author's experiments negative the time-honored myths that light meats are safer than dark ones, that milk is always and everywhere the best diet, and that the kidneys will be improved by a flushing out with unlimited quantities of water. The subjects are treated under the headings: the customary therapy of kidney diseases, the principle of saving the kidneys in renal diseases, the facts of metabolism as a basis of dietary regulations for the protective therapy of kidney disease, the principles underlying dietetic and physical treatment of acute nephritis, and those underlying the same in contracted kidney. Not only are the questions treated with scientific precision, but the data are presented in an eminently practical manner, and, everything considered, this work is one of the best treatises we have seen upon the treatment of these diseases. The translation, while always intelligible, is not in every case happy, and it presents some solecisms. The proof-

reading also is at times at fault, *e. g.* at the bottom of page 68, where one, or more, lines are omitted.

Physiology. A Manual for Students and Practitioners. By Theodore C. Guenther, M.D., Assistant Physician, Norwegian Hospital, Brooklyn; Chief of Medical Clinic, Norwegian Hospital Dispensary; Member of King's County Medical Society, and Augustus E. Guenther, B.S., Formerly Assistant in Physiology in the Medical Department, University of Michigan. Philadelphia and New York: Lea Brothers & Co., 1903.

This little volume appears to be suited for the purpose intended—namely, to give briefly, clearly and satisfactorily the main points in physiology such as would be useful to medical students. The definitions and explanations are all well given, and the text is not interrupted by the usual paragraphing of the quiz-compend, the necessity of self-examination, however, being recognized by a set of questions at the end of each chapter.

The Internal Secretions and the Principles of Medicine. By Charles E. de M. Sajous, M.D., formerly Lecturer on Laryngology in Jefferson Medical College, formerly Professor of Anatomy and Physiology in the Wagner Institute of Science, etc. Vol. I. Philadelphia: F. A. Davis Co., 1903.

This volume forms the first of a series, the second of which, upon pharmacodynamics and physiological pathology, is announced to appear shortly. The present volume is in the nature of a monographic, classified marshalling of the data contained in the literature, in support of the author's very decided views upon the importance of the so-called ductless glands, in particular the adrenal system and its governor, the anterior pituitary body, and the relations to the latter, in the way of necessary stimulant, of the thyroid gland; and of the posterior pituitary body as the functional center of the nervous system. Also the relations of the adrenal system to the general motor system and the pneumogastric nerve, and that of the internal secretions in their relation to immunity, with particular reference to the protective rôle of the leucocytes, are discussed. The work is well illustrated by full-page plates, many of them colored, and, as in all of Dr. Sajous's work, the data are arranged with a view to the maximum of convenience in reference, an analytical table of contents and a good index being given. The book thus forms a mine of information collected from the immense scattered literature of the world.

Experiments on Animals. By Stephen Paget, with an Introduction by Lord Lister. New and Revised Edition. London: John Murray; New York: G. P. Putnam's Sons, 1903.

Considering the urgent need for an authoritative, yet popular, exposition of the results actually obtained from experimentation on animals, as a refutation of the hysterical distortion, perversion, and exaggeration, put forth by the antivivisectionists, no book is more opportune than the one now under consideration. It is to be hoped that this sober, matter-of-fact presentation will carry conviction among the laity upon whom, in the last analysis, we must depend for the rejection of the appeals constantly being made upon sentimental grounds to our Legislatures for the restriction of scientific research. In the present edition some mistakes have been corrected and some recent facts added. References in the first edition to false statements of the antivivisectionists, have been omitted from this edition on the ground that the space necessary for their refutation can be better employed. The book is, of course, an armamentarium of evidence in which fact after fact is marshalled into a convincing array, showing that practically all of modern medicine, physiology, pathology and treatment is the outcome of experimentation on animals. For its author it is, as Lord Lister says, entirely a labor of love.

Die Krankheiten des Kehlkopfs. Von Dr. M. Bukhofer, Konigsberg. Berlin: August Hirschwald, 1903.

This book purports to be an introduction to the general study of laryngology. It opens with the usual chapters on anatomy, physiology, methods of examination, causes of laryngeal disease, and general therapy. Then follows chapters on individual diseases. Nothing new is presented, but an effort is made to view the various topics, especially from the standpoint of the advances of the last five years. Numerous references are made to the original publications of standard authors, the bibliographical list containing nearly six hundred entries. The book is not illustrated at all. The author considers such a thing unnecessary for three rather peculiar reasons: First, each student probably owns an anatomy; second, illustrations of pathological conditions are best studied in atlases on pathology, and third, as for instruments, why you can see in any instrument maker's catalogue all the pictures of instruments you want. The publication of this manual is no addition to the valuable literature of laryngology.

Transactions of the American Surgical Association. Vol. XX. Edited by Richard H. Harte, M.D., Recorder of the Association. Printed for the Association by William J. Dornan, Philadelphia, 1902.

This annual volume contains the usual collection of well-selected papers upon surgical subjects, which have been discussed in the journals and at society meetings during the past year. It is not really necessary to pick out any particular paper for extended comment, since all have merit, and those who follow surgical literature are probably already familiar with them. The volume is well put together and is worth keeping for reference.

Selected Papers on Operative and Clinical Surgery. By the late William Stokes, M.D., M. Ch., F.R.C.S.I., Kt., Surgeon in Ordinary to Her Majesty, Queen Victoria, in Ireland, etc., etc. Edited by William Taylor, B.A., M.B., F R.C.S.I., etc., etc. With a Memoir of the Author by Alexander Ogston, M.D., Regius Professor of Surgery, University of Aberdeen, etc. London: Baillière, Tindall & Cox, 1902.

The collection of papers in this volume represent the experience and ideas of a well-known British surgeon, who went to South Africa during the late war and died there—possibly in consequence of the strain and exposure to which he was thus subjected. The essays are upon a variety of subjects and their literary merit is great. While all are interesting, those devoted to African experiences will attract most attention from the reader, who will get from them a vivid idea of what the surgeon has to contend with in war. Professor Ogston's appreciative memoir adds much to the interest of the volume, and the text of the papers contains much clinical report and discussion of cases, which have come under the care of the author.

Chirurgie Intestinale d'Urgence. Par Albert Mouchet, Chef de Clinique Chirurgicale à la Faculté de Médecine de Paris. Paris: J. B. Bailliere et Fils, 1903.

This little hand-book is one of a series (Les Actualités Médicales) in which a number of excellent monographs has appeared. The present volume is designed to afford epitomized and accurate information for the student, and also for the practitioner who may be confronted with abdominal conditions requiring prompt and radical treatment. Some of the subjects discussed are strangulated hernia, intestinal obstruction, and appendicitis—a pretty large field to be enclosed in one hundred pages. The author, however, has confined himself to categorical statements and hard and fast directions, avoiding entirely long discussions and pathological detail, and his efforts have produced a useful book.

The Anatomy of the Human Peritoneum and Abdominal Cavity, Considered from the Standpoint of Development and Comparative Anatomy. By George S. Huntington, M.A., M.D., Professor of Anatomy, College of Physicians and Surgeons, New York. Illustrated with 300 full-page Plates. Philadelphia and New York: Lea Brothers & Co., 1903,

The volume before us is the product of a number of years of work by its author who has been led far afield, from the point of view of the physician, in his morphological studies. It is necessary to examine the book in order to understand what an enormous amount of work has been done in order to place it before the reader and the author is to be congratulated upon his industry. The peritoneal anatomy of at least one species from almost every family or group of families is described and illustrated in a way that leaves little to be desired, and the relations to the human being to the various points are discussed. The information is of the most detailed kind, and is such as is welcomed by the special worker, but is not of much use to the average physician. The make-up of the volume is good, and it will please the limited class for whom it is intended.

Consultations sur les Maladies des Voies Urinaires a l'usage des Praticiens. Préface par le Docteur Tuffier, Chirurgien de l'Hôpital Beaujon, Professeur agrégé a la Faculté de médecine de Paris. Avec 110 Figures intercalées dans la texte, par G. de Rouville, Professeur agrégé a la Faculté de Médecine de Montpellier. Paris: J. B. Baillière et fils, 1903.

This work of less than 300 pages presents all the accepted recent methods of healing with genitourinary affections, and, besides the usual illustrations of instruments, shows some of the ways in which they are used. It is especially adapted for the use of general practitioners, and those reading French will find it useful.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

THURSDAY, MAY 14—MORNING SESSION.

A Preliminary Report on the Influence of Alcohol in Infectious Diseases.—Dr. H. A. Hare of Philadelphia read this paper, showing that the administration of alcohol to patients suffering with infectious diseases had a marked action in that it increased the bacteriolytic action of the blood. The bacillus coli communis was very readily killed by the blood serum of these patients. Therefore it was held by the essayist that in this manner the administration of alcohol had a marked beneficial action in the treatment of infectious diseases.

Infantile Scorbutus.—Dr. J. M. Rotch of Boston read this paper, and reported in abstract cases of a peculiarly grave type, and insisted upon the importance in differentiating osteosarcoma from osteomyelitis. In one case there was a subperiosteal hemorrhage throughout the whole length of the tibia, giving it the appearance of osteomyelitis. Operation was performed and large sequestra were removed. Rapid improvement followed the administration of orange-juice. Inasmuch as new bone tissue was now forming in the site of the operation wound, a complete and speedy recovery was expected. In a second case, of a baby, nine months old, large swelling and hardness of both femora made a differential diagnosis from osteosarcoma somewhat difficult. The administration of orange-juice was followed by complete recovery.

Sudden and Unexpected Death in Infancy and Childhood, with Special Reference to the So-called Thymus Death.—Dr. J. P. Crozer Griffith of Philadelphia read this paper, and referred to death in infants due to coryza, holding that these patients really died in the early stages of laryngismus stridulus. He cited a case in an infant six months old, which had been ill, but had so far recovered that the author had told its parents that it would get well. There was present, however, very rapid breathing, which progressively increased, and in a few hours the child died. There was no fever at the time. The essayist reported in detail two cases of thymus death that had come into his practice, and thought that the sudden death was due to pressure of the gland upon the trachea, heart, or blood vessels. It was possible that the real cause might have been dependent upon the nervous system and the existing status lymphaticus was but an anatomical manifestation. Although Gravitz held that death in these cases was due to pressure, there were but three cases in literature to substantiate this theory.

Dr. Abram Jacobi of New York said it was useless to generalize in cases of thymus death. There were conditions causing death in the first stages of laryngismus stridulus and apnœa. In some of his cases autopsy had shown a marked diffuse congestion to be present in the meninges and spinal cord.

Studies on the Action of Alcohol upon the Circulation in Fevers.—Dr. Richard C. Cabot of Boston read this paper. The question of interest in the present day, after so much experience of a clinical variety, was, What was the true action of alcohol on the circulatory system? and not that as to whether it was beneficial. There had been but few experimental studies of this nature upon the human being. The investigations were based, in the author's cases, upon the variations in the blood-pressure during diastole and systole. He had taken these pressures two days before the administration of the drug and then gave the patients (forty in number) four, six, eight, and twelve ounces during the next two days, and then discontinued the drug, continuing to take the blood-pressure for several days following the discontinuance of the same. It had always been taught that following the administration of alcohol in fevers there was first a transient rise in the blood-pressure with a subsequent depression. The author's experiments proved that these changes would take place even without the administration of alcohol, hence he considered them of no vital importance. The Oliver instrument had been employed to take the diastole pressure, while the Riva-Rocci apparatus was employed to estimate the changes in the systolic. In a young girl with typhoid fever, who had been taking sixty ounces of champagne in twenty-four hours for a period of six weeks, the sudden cessation of the alcohol had not the slightest effect upon the blood-pressure curve. It was concluded from the results obtained by these experiments that the administration of alcohol in fever cases, in no way influenced the blood-pressure, either during systole or diastole.

Dr. Wm. H. Welch of Baltimore said that Abbott and others had clearly proven that alcohol given to animals, almost to the state of intoxication, increased their susceptibility to bacterial infection. Rabbits which were able to overcome the introduction of bacteria of low virulence would easily succumb to the same organisms if they were kept under the influence of alcohol for a short while. However, alcohol was beneficial in cases of collapse. It had been completely demonstrated that in large doses the bacteriolytic action of the blood was diminished. The colon bacillus which Dr. Hare had used in his experiments were very readily destroyed by ordinary normal blood serum in the same length of time that it had taken to destroy them in the alcohol immunized animal. Hence the experiments proved but little as to the increasing of the bacteriolytic action of the blood by alcohol. He did not think that there was any relation between the bacteriolytic action of the blood serum and susceptibility. That up to the present time no experiment regarding the administration of alcohol had been performed which was in any way conclusive.

Dr. Jacobi of New York City remarked that Dr. Hare's paper taught nothing new as far as the clinicians were concerned. He had always given alcohol in large doses in cases of septic fevers. He did not hesitate to administer as much as one pint to a child. A curious point was that as long as sepsis was present there would be no intoxication, but just as soon as the system recovered from the influence of the sepsis the alcohol made the child drunk.

Dr. A. C. Abbott of Philadelphia had found that where there had been an increase in the hæmolytic condition there would be present in some portion of the body areas of inflammation.

Dr. F. C. Shattuck of Boston said that clinical evidence was so greatly in favor of the beneficial action of alcohol in fever cases, that it was up to experimenters to prove more conclusively than they have been so far able, that the contrary was the true state of affairs.

Dr. Dock of Ann Harbor had been able to cure many cases of sepsis without the administration of alcohol, nence he did not believe it was essential in such cases.

Dr. Cabot, in closing the discussion, said that the number of physicians using alcohol as a stimulant was rapidly diminishing.

The Morbid Changes in Hereditary Ataxia.—Dr. L. F. Barker of Chicago read this paper and said that the disease was most commonly found between the sixteenth and forty-fifth years. The sexes were equally often attacked, though the descent was more often through the female side of the house. The ataxia was of the cerebellar type. The movements were sluggish, and when the patients were first attacked they were often supposed by their acquaintances to be under the influence of alcohol. Romberg's sign was absent. There was defective vision, and the speech was defective because of incoördination of the muscles of the tongue. The two cases reported by the speaker were brothers. The first case started when the patient was but twenty years old, and he died as the result of great emaciation and general inanition. The disease started in the second brother at the age of twenty, and he died ten years later of pulmonary tuberculosis. The findings at autopsy were of the same character, but one was in a more advanced stage than the other. Both brains

showed excellent fissuration. The brain and spinal cords were somewhat smaller than normal. The cerebellum was larger than the rest of the brain, but proportionately well developed. Microscopic sections showed degeneration of the direct cerebellar tract and of Clark's nucleus. In the more advanced case the terminals and collaterals had disappeared. In the posterior funiculi the degeneration did not involve the whole root. In the lumbar region there was degeneration of the middle zone. In the thoracic region the median portion of the cuneatus was involved. The cervical region showed disseminated areas of degeneration throughout the ventral and median portions of the gracilis, while the dorsal portion of the cuneatus was normal. The author believed that this degeneration corresponded quite closely to the third fetal system of Trepinski. It was a disease of a neurone chain, thus depriving the cerebellum of the tract through the third fetal system. The cerebellum on section proved to be practically the same as normal. A third case of Dr. Sanger Brown's cases, upon which an autopsy had been performed under the supervision of Dr. Adolph Meyer of New York, showed the same condition of degeneration as was described by Dr. Barker.

Autolysis in Lobar Pneumonia.—Dr. Simon Flexner of Philadelphia read this paper, remarking that although Salkowski, in 1882, showed that organs which had been removed from the body underwent self-digestion, this fact had been lost sight of until very recently, when the pupils of Hoffmeister reviewed the subject and showed that the autolysis was due to ferments. Dr. Flexner had shown that exudates would act in the same manner, outside the body, provided bacteria were eliminated. In the body the exudates underwent an emulsifying transformation which rendered them more suitable for the process of absorption. The ferments were contained in the leucocytes. Thus, in lobar pneumonia, there were certain cases which failed to undergo resolution, and in these the author found that there was less autolysis than was present in the general routine of cases. In those cases in which the autolysis was rapid the exudate consisted largely of cellular elements, while in unresolved pneumonia the exudate was largely fibrinous, which could but feebly undergo the emulsifying transformation. Eventually, the fibrinous exudate was absorbed by the process called organization, in which the leucocytes invade the fibrinous exudate coming into it from the new-formed vessels and thereby setting up autolysis, and assist in the absorption of the fibrinous exudate. This latter process is in reality true autolysis in an indirect manner, but by this method the lung is left permanently pathologic.

The Adrenal Gland and Its Active Principle in Relation to Cystoclysins and Antitoxin Production.—Dr. A. C. Abbot of Philadelphia read this paper. Experiments with the injections of ferri-chloride into rabbits killed them in eight hours. Later the sera of these animals which had been preserved aseptically were injected into guinea-pigs, and no changes were discoverable in the adrenal glands of these animals. The serum was hæmolytic, however, and the pig most promptly died. The serum of rabbits immunized from erythrocytes, gave the same hæmolytic results as serum immunized from adrenals. In no case was the adrenal gland of the guinea-pig demonstrably affected, beyond a more or less congestion, by the intraperitoneal injection of serum of rabbits that had received repeated injections of guinea-pig's adrenals. The serum of rabbits treated with guinea-pig's adrenals was, *in vitro*, not only hæmolytic, for guinea-pig erythrocytes, but caused more or less agglutination of fresh macerations of the adrenal glands. The serum of rabbits immune from guinea-pig's adrenals differs from that of rabbits immune from guinea-pig's blood in being less toxic. It was impossible to determine the minimum lethal dose of the active principle of the adrenals, because of the remarkable variation in susceptibility of the rabbits to its toxic action. It was possible, however, to render these animals immune from this substance by repeated small doses. The injection of epinephrin obtained from Dr. J. J. Abel resulted in a tolerance but not an immunity.

Experimental Study of the Nephrotoxins.—Dr. R. M. Pearce of Philadelphia read this paper. Transient albuminuria was produced in nine animals in which the ureter on one side was tied, as it was in the cases of nine others in which the vessels supplying the kidneys were ligated. The same results were obtained after a one-sided nephrectomy. In none of these were there present tube casts, and the histologic examination of the remaining kidney was absolutely negative for pathological changes, not even a disappearance of the cell granules. The blood serum of these animals injected into others in the proportion of one part of serum to two hundred by weight failed to produce nephritic changes in the kidneys of the injected animals. Emulsified kidneys were injected into dogs and then the dog's blood serum was injected into another dog, with the production of hæmoglobinuria and tube casts. These results were not due to the hæmolytic action of the blood contained in the kidney emulsion, for that had previously been washed out of the kidney. Histologically, there was fatty degeneration of the kidney substance, especially in the descending loops of Henle. The serum had no effect upon the blood-pressure, which would tend to show that nephritis, with its concomitant rise of blood-pressure, was not a factor in the production of cardiac hypertrophy. Some of the dogs which the author had secured for experimentation were found to have a spontaneous nephritis. The serum of these dogs, when injected into perfectly healthy animals, produced, in sixteen to twenty hours, a true nephritis. In turn, the serum of this animal produces the same condition in a third animal.

Studies upon the Capsule of the Kidney.—Dr. S. F. Meltzer of New York City read this paper for Dr. Haven Emerson of the same city. Immersion of the kidney before decapsulation, in a solution of the iodide of potassium, failed to develop the drug in the urine; but if immersion were practised after the decortization were done, the drug was readily demonstrated in the urine. These experiments would tend to show that the capsule of the kidney acted as a protection against infection of and the ingestion of metabolic substances from the neighboring organs. In rabbits, whose kidneys had been decorticated, there was no evidence of the presence of new-formed blood vessels, as had been shown by Edebohls. In dogs, however, in which the operations had to be performed intraperitoneally and in which there was no peritoneal fat, adhesions were found to exist between the liver, pancreas, and other organs.

Report of a Successful Decapsulation of the Kidney.—Drs. James Tyson and Chas. H. Frazier of Philadelphia read this paper. In the case of a child of nine years who had nephritis for four years following scarlet fever, in which there was extreme œdema of the extremities, after all methods of medication had failed to relieve the condition and death seemed impending, decortication of one kidney was performed. Previous to the operation, the urinary output was but a few ounces in twenty-four hours, whereas in twenty-four hours following the operation, the patient voided 100 ounces. Ten days after the operation all the œdema and ascites had disappeared, and the patient was passing the normal quantity of urine. Albumin and casts were still present, though in much smaller amounts. Two months following the first operation the second kidney was decorticated. The patient was kept in bed for three weeks, and on getting out, the amount of albumin and casts markedly increased, so that it was necessary to return her to her bed At the present writing the patient is up and about, but still has some albumin, and a few hyaline casts in her urine The operation effected its good results by producing a temporary improvement in the renal circulation. The removal of the kidney capsule relieved the tension, thus permitting more blood to enter the organs and be

depleted of its watery elements. The operation was to be advocated in extreme cases, and it was to be considered an advance in kidney therapeutics.

Dr. Cutler of Boston reported three cases of this kind. The first died at the end of six months, while in the second there was a regeneration of the capsule about the kidney. The third case was that of a boy with post-scarlatinal nephritis. The operation was followed by marked improvement, but there was a condition of chyluria, which had now passed off. At the end of a year improvement was still progressive and the lad had grown considerably and looked the picture of health.

Dr. Tyson, in closing, thought the operation much more suited to children than to adults.

Paroxysmal Hæmaturia.—Dr. Wm. Gilman Thompson of New York City read this paper, and reported two cases of this variety, one which had been known to have existed sixteen years and the other for fourteen years. The attacks were brought on in both cases by slight exposure to cold and fatigue. These attacks would start with a chill, rise in temperature to 103°, marked urticaria, disturbances of sensation, and with numbness. One hour after the outset the patient would pass dark-colored, smoky urine, which became progressively darker at each voiding. On one occasion the second patient developed hydrops articulorum. In neither case was there jaundice. In the second case, a boy, it was found that the exposure of one of his hands to a temperature of 60° would induce an attack. Two hundred and six cases were to be found in literature. The important points in the disease were the presence of hereditary syphilis, urticaria, etc. The condition was rare in the United States. It was a disease of the nervous system, and the presence of a neurotic temperament and alcoholism in the parents were important points in the predisposing causes of the disease. Males were more often affected. Few cases were reported after the sixtieth year. It was commonest in the fourth decade. It was never fatal or associated with hæmophilia. Temperature not easy to explain and it might go on to 105°. It was not due to malaria. Pain was constant and radiated into the bladder, and the spleen and liver were enlarged. There was almost always an albuminuria preceding an attack. Many cases were induced by muscular fatigue, especially walking, as was seen in soldiers. Information gained from autopsy was of little value. Hereditary syphilis was the most important etiological factor in the disease. In closing, the doctor defined the disease as a vasomotor neurosis, called into play by exposure to cold, fatigue, or mental emotion.

THURSDAY, MAY 13—AFTERNOON SESSION.

Observations on Some Points in the Pathology of Thyroid and Parathyroid.—Dr. W. G. McCallum of Baltimore read this paper, and found that extirpation of the thyroid gland was not alone accountable for the tetanic symptoms which were recorded as appearing after the operation. In the experiments carried on by the author the dog and goose were chosen as the most convenient for the work to be done. Emulsion of the thyroids and parathyroids were injected into the goose and the serum of the bird was injected into the dogs. The larger majority of the dogs remained perfectly unaffected, but one was in some time decidedly cachectic and developed conjunctivitis. In others there were choreiform movements from the thyroid immune serum, and later the dog died. Autopsy showed some cellular disintegration, but the thyroids practically normal. The parathyroid in some instances gave cachexia and slight tetanic movements. But the parathyroids showed no pathologic changes. It had been long known that the extirpation of the parathyroids produced certain acute symptoms, in the speaker's experience, and this was shown to be true. The dog remained well for two or three days, and then showed anxious expression, with fibrillary contractions of muscles, which grew progressively worse. Respiration increased to 200 per minute. There was retraction of the upper eyelids, as was seen in exophthalmic goiter. Later the respiratory curve slowed down, and the dog died. Sometimes the attacks were epileptiform. The respiration in some instances became Cheyne-Stokes in character. There were no acute symptoms from the extirpation of the thyroid alone. The theories as to the function of the parathyroids were as follows: (1) That they furnished some secretion necessary for the body, (2) or that their secretion destroyed the toxins produced in other organs. The introduction of normal blood by transfusion caused an abatement of the acute symptoms in the tetanic dog. The introduction of salt-solution into the veins of these dogs produced the same results, hence it was argued that there must have been some poison in the tetanic dog's blood which was diluted by the infused normal blood and saline solution. Section of the spinal cord was done and the goose serum injected into the dog. There resulted a tetanic condition in the upper portion of the body, while that below the point where the cord was severed remained almost flaccid, except for slight fibrillary contractions. In the light of these experimental results, Mr. McCallum concluded that the poison had its chief effect upon the central nervous system, and more especially upon the higher nerve centers. That there was no anatomical relation between the parathyroid and the thyroid glands. In the autopsies on exophthalmic goiter cases in the pathological department of the Johns Hopkins Hospital, it had been found that the parathyroids were either absent, or exceedingly small. The speaker had under observation one case of exophthalmic goiter to whom he was feeding the extract of parathyroids. In the last two weeks he had been unable to observe the slightest effect upon the patient, one way or the other.

The Influence of Different Varieties of Fat on the Formation and Excretion of Acetone.—Dr. E. P. Joslin of Boston read this paper. Experiments had recently been made to find out the influence on the excretion of acetone by the ingestion of the various varieties of fat and fatty acids in the cases of diabetics. The modern theory of the production of coma and other manifestations in diabetes had led to this line of investigation. The examination of a control case of this disease showed the presence of but 10 mg. of acetone in the urine two days previous to the administration of 200 mg. of oleic acid. Twenty-four hours following the ingestion of the drug there were over 1,700 mg. found in the urine. Palmitic acid gave no results, but the sodium salt of the drug was found to be better absorbed and gave the same results as the oleic acid. The glycerinate of palmitic acid and oleic acid also increased the output of acetone to a marked degree. The writer agreed with Van Noorden that it was not well to cut off any one variety of fats. If fats were to be administered at all, they must be given very slowly, in order that they might not produce too great an amount of acetone in the system at one time.

Pulsating Empyema Necessitatis.—Dr. F. P. Henry of Philadelphia read this paper, prefacing his remarks with an apology for presenting a purely chemical paper before the association. The case which was reported had first come under observation in 1880, but had never before been reported in full. It had been referred to by Osler and Wilson on various occasions. There were three strongly pulsating tumors. The only other case with as many tumors was the one of Chevostek, which figured as No. 28 of Wilson's series. There had existed a coincident pneumothorax. Aspiration had been performed, with subsequent drainage. The patient was living one year after the operation. The case had presented some points similar to an aneurysm. At the end of the paper there was appended fifteen cases not included in Wilson's series, collected from literature, making in all, eighty-three cases.

Dr. McPhedran of Toronto reported a case of this variety which had occurred in his practice, in which the turning of the patient on his back caused a pulsation in the

right axilla, and when the patient was turned on his right side the pulsation occurred in the back and disappeared in the axilla. The fluid was up to the fifth rib, and the apex beat was not at all changed in its position, which showed that its pericardium was fixed to the body wall.

Dr. HENRY concluded by saying that the only other case that he had seen that resembled this one was a case of aneurysm which had ruptured into the pleural cavity.

A Case of Extensive Pulmonary Infarction.—Dr. A. MCPHEDRAN of Toronto asked permission of the society for Dr. J. J. Mackenzie of Toronto to read this paper, inasmuch as this gentleman had done the work. Permission was granted, and the case was reported as follows: there was complete infarction of the middle lobe and the lower third of the upper lobe. In the left lobe there were several areas the size of a half dollar, showing beginning infarction. In the pulmonary artery just above the valve, there was a definite change, with a round-cell infiltration and an extensive endarteritis of the vessels about the size of a pencil on the right side, which was ascribed as the cause of the trouble. These vessels were thrombosed. In the lumen of some of these arteries there was deposited fibrin. There was but little sclerosis of the infarcted middle lobe. The process in the upper lobe seemed to be the oldest. The heart appeared to be perfectly normal, showing no lesion of any pathological character. In the liver was seen the true cause of the trouble, as there were present numerous miliary gummata, and undoubtedly the process in the arteries was of a luetic origin.

A Case of Presystolic Mitral Murmur Complicating Pregnancy, etc., with Exhibition of a Specimen Showing Triple Valvular Lesion.—Dr. JAMES TYSON of Philadelpha read this paper. The case had first been reported in May, 1899, and, again, in May, 1901, and the concluding report was now presented, with an exhibition of the heart, which showed a triple lesion; namely, tricuspid stenosis, aortic stenosis, and mitral stenosis. The aortic stenosis had not been recognized before the death of the patient. This had so often been the case in this sort of cardiac lesion.

Experimental Studies on the Eosinophilia of Trichinosis; a Preliminary Report.—Drs. HERBERT U. WILLIAMS and CHARLES A. BENTZ of Buffalo read this paper. Animals infected with trichinosis did not produce a true eosinophilia, nor were there many eosinophiles about the parasites which were present in the tissues of the animal. An extract was prepared from fresh pork containing numerous living trichinæ previously digested with artificial gastric-juice. The residue, which contained many worms, was collected, washed, dried, and inserted into the peritoneal cavity of cats, dogs, and frogs. Great numbers of eosinophilic leucocytes were collected after several days, near the point at which the worms were introduced, in a large proportion of the cases. This action was probably due to some unknown substance contained in the bodies of the worms. Other substances introduced, produced no such action of the eosinophilic leucocytes

This paper concluded the scientific part of the meeting, and the President announced that the council had nominated the following officers: *President*, Wm. T. Councilman of Boston; *Vice-President*, Dr. Edward L. Trudeau of Saranac Lake, N. Y.; *Secretary*, Dr. Henry Hun of Albany; *Recorder*, Dr. Solomon Solis Cohen of Philadelphia; *Treasurer*, Dr. J. P. Crozer Griffith of Philadelphia; *Councillors*, Drs. Victor C. Vaughan of Ann Arbor, Mich., and George M. Kobero of Washington, D. C , who were unanimously elected by the association. On a motion to adjourn, which was duly seconded, the President dismissed the society, to convene next May, at Washington, D. C.

Bats and the Plague.—During the occurrence of bubonic plague at Naples some months ago, it was suggested that the disease might be spread through the instrumentality of bats. It was found that these animals were remarkably susceptible to the disease, even more so than rats.

AMERICAN GYNECOLOGICAL SOCIETY.

JOSEPH E. JANVRIN, M.D., NEW YORK, PRESIDENT.

SECOND DAY, WEDNESDAY, MAY 13.

Discussion.—The Etiology, Pathology, and Treatment of Puerperal Sepsis.—In the absence of Dr. HIRAM N. VINEBERG of New York, who was to read this paper, Dr. J. Riddle Goffe of New York presented an abstract of it: (1) Severe puerperal sepsis might be caused by a variety of pathogenic germs. The variety of germ found in the uterine discharges in a given case was no criterion of the severity of the case and formed no safe guide as to prognosis or as to the treatment to be adopted. (2) Bacteriologic examination of the blood was of little value, either from a prognostic or therapeutic standpoint. (3) The treatment of puerperal sepsis had to be based chiefly upon the clinical history and physical signs of each individual case. (4) Wounds of infection in the perineum, vagina, or cervix were to be treated on general surgical principles of irrigation and drainage. (5) Curettage was indicated when there were evidences of placental decidual residue in the uterus independent of the variety of bacteria that might be found in the uterine cavity. (6) In those rare cases in which adherent and sloughing placental tissue could not be removed, either with the sharp curette or fingers, hysterectomy was indicated, providing the patient was not already moribund. (7) Hysterectomy was also indicated in septic endometritis, or infection of the placental site, so long as the infection was still limited to the uterus, and when the symptoms steadily grew worse in spite of uterine irrigations, with or without curettage and appropriate hygienic stimulating treatment. (8) In abscess of the uterus the abdomen should be opened, and when feasible the purulent foci were to be drained and the uterus preserved. If the uterus were studded with small abscesses, hysterectomy was indicated. (9) The abdominal was to be preferred to the vaginal route for hysterectomy. (10) If the infection passed from the uterus into one or other tube and set up a violent grade of inflammation, the abdomen should be opened and the infected tube removed before a general peritonitis developed. (11) When the infection passed through the uterus and set up a general peritonitis, a case might occasionally be saved by a timely abdominal section and drainage. (12) In cases of parametric exudates the treatment should be of a conservative nature, and surgical intervention was indicated only when there were evidences of pus formation. (13) In obscure cases, in which the pathological lesion could not be determined, and the symptoms were steadily growing worse, it might be advisable to open the abdomen to search for a hidden purulent focus, or for a circumscribed slough of the uterus. (14) The procedure proposed by Trendelenburg, and executed by him and others, of ligating the pelvic veins when they became infected and thrombotic, was worthy of further trial.

Dr. WILLIAM R. PRYOR of New York stated that cases of puerperal infection which demanded attention generally had streptococci. Mortality raised from 2 to 27 per cent., according to the variety of streptococcus. Streptococci occurred about the time of a chill. In other cases they were not to be found. Their occurrence was a bad standard of treatment. There must be decided indications for it, before curettage was attempted. Lesions of puerperal septicæmia were local. Curettage disseminated the infection. The mortality in cases which had been curetted was 22 per cent. It was considerably increased by this treatment. When a patient suffered from septicæmia, hysterectomy was contraindicated. The speaker then related the results of some experimental work in which he has been interested for the last six months. In cases in which streptococci were in the uterus, and the posterior cul-de-sac was opened, pure cultures of the streptococci were found there, and no other microorganisms. He then spoke of the effect of iodine in the treatment of these cases. Disintegration of iodoform was rapid. It could be detected

in two or three hours in the urine. There was a rapid abatement of untoward symptoms after its administration. It was never found in the blood. The hæmoglobin was raised after its use. There was something in the aqueous solution of iodine which, for the time being, would prevent infection by the streptococci. In experiments on rabbits, as long as the injection fell short of a lethal dose of streptococci, the injection of iodine saved the rabbit's life, as no animal had died under these circumstances.

Dr. Cragin of New York said that he had lost some cases in hospital practice in which the streptococcus had not been found. Streptococci were found in the severest cases. He called attention to two points in treatment. These were, to make sure that the uterus was empty, and to do as little injury to the uterus as possible. Curettage could be either manual or instrumental. The former was preferable. He did not believe in letting the patient alone till he knew that the uterus was empty. If the finger did not suffice, then he used the curette. Patients suffering from toxæmia or sapræmia, were just ready for a septicæmia if not relieved.

Dr. Whitridge Williams of Baltimore thought that bacteriological examination was valuable. In many cases it gave no definite indications for treatment. But much information was gained by it, and much light was thrown on the prognosis. If in the presence of severe symptoms streptococci were found in the uterus, then the patient's condition was alarming. If the microorganism was found to be the gonococcus, or colon bacillus, or the putrefactive organisms, even though the symptoms were similar, still anxiety was relieved. He depended, to a great extent, upon this examination. When streptococci were found in the blood, then the condition was serious, but not necessarily fatal. In cases of streptococcic infection, curettage was undoubtedly harmful. He never used curettage in those cases, but gave a sterile douche and let the patient alone. The only time he used curettage was in certain cases after abortion. As to operative treatment, its field was very limited in these cases. In case of abscess in the uterine wall, hysterectomy was indicated. He had had only two cases in which operation was indicated. In one there was adherent placenta with profound infection. The patient declined operation and died. In the second case there was a thrombus in the vessel going off from the right of the uterus. Operation resulted in recovery. Conservatism was needed here. There should not be indiscriminate operating. He did not believe in Tuffier's view on this subject.

Dr. Matthew D. Mann of Buffalo said that gonococcus infection generally showed itself late—on the tenth day, or even later. It was generally not severe. He had had excellent success in these cases from a solution of silver nitrate, injecting it even into the vein. The treatment had to be pushed to its utmost limit.

Dr. Gill Wylie of New York believed in emptying the uterus and washing it out even if saline solution only was used. Drainage was very important if any material was left in the uterus. He used special forceps in those cases in which the fingers did not suffice. He used repeated washings till the uterus was cleared of débris.

Dr. Davis of Philadelphia believed in evacuating pus wherever formed. He used a blunt curette to clear the uterus.

Dr. McLean of New York believed that mortality was enormously increased by currettage. The curette in the average hand was a dangerous instrument. He doubted the propriety of repeated washings of the uterus. He considered the use of the intra-uterine tube dangerous. He recommended the use of iodine. He used the compound tincture of iodine, by wetting a cotton sponge and carrying it up into the uterus for a few minutes. The iodine coagulated the products which caused the trouble; it was a germicide, and it was soluble, being found in the urine and saliva in a few minutes after administration.

Dr. Fry of Washington advised letting the uterus alone in streptococcus infection. A curette could not reach it. Nature threw out a protective zone which a curette would break down, so producing a general infection. He advocated the use of rubber gloves.

Dr. Robert Murray of New York called attention to the necessity of cleansing the vagina. Lesions were often found there.

Dr. Boldt of New York did not believe that bacteriological examination gave the clue as to treatment. He did not think that much advancement had been made in the treatment of puerperal sepsis in the last ten years.

Dr. Gordon of Portland thought that surgical treatment was apt to be too early. Whenever an abrasion was made, unless the operator went straight to the point of infection, he was starting a new point of infection. He believed in repeated washings with salt-solution, and in large, frequently repeated doses of quinine. Quinine was a most valuable remedy. He did not believe in using the curette.

Dr. Wetherell of Denver advocated the use of the alcohol method of Carosso. Its success depended upon the localization of the original point of infection and upon drainage, not with gauze, but with a tube. These infections should be treated like other infections. He used for this irrigation a large, double current rubber tube which went to the fundus. The alcohol was from 50 to 100 per cent. It was non-toxic.

Dr. Pryor concluded the discussion by saying that more women died now of puerperal sepsis than before the introduction of Lister's method. Statistics showed that of all deaths of females, 1 per cent. was from puerperal sepsis.

Repetition of Cæsarean Section on the Same Patient: the Experience of the Boston Lying-in Hospital.—Dr. Charles M. Green of Boston delivered this paper. Of 50 Cæsarean sections in the last 9 years, 9 were repeated operations, performed on 8 patients; second sections had been done on 8 women, and in 1 case section had been repeated twice. He then gave a résumé of these cases. Two of these were done after labor had been in progress for 9 hours each, and 7 at an elected date before labor began. In 1 case there were no adhesions; in 7 cases there were more or less adhesions, and the duration of the operation was from 39⅓ minutes to 1 hour and 24 minutes; in the case that died of shock the duration was 48 minutes. In 1 case the utero-abdominal adhesions were so extensive that the fœtus was delivered without opening the peritoneal cavity, and the time of operation was 38 minutes. The 9 infants were discharged well, and of the 9 mothers, 1 died, a maternal mortality of 11 per cent. He reported these results in the hope of influencing opinion that the time had come when this society should withhold its approval of the doctrine that women should be sterilized at their first Cæsarean operation, in order that they might not be subjected to the risks of a repeated section. It was conceded that in the presence of serious disease of the uterine appendages, surgical judgment might properly decide on their removal that the time of performing the Cæsarean section; it was conceded that when the uterus was believed to be already infected, total hysterectomy might give the patient an improved chance of recovery; and it was conceded that hysterectomy was justifiable in the presence of fibroids so situated that they could not be subsequently removed by myomectomy without sacrificing the uterus. It was also granted that, in the rare event of the uterus failing to contract, and of serious, otherwise uncontrollable hemorrhage ensuing, it was justifiable to tie off the uterus and remove it. It was probably true that after hysterectomy convalescence was quite as rapid as when the uterus was sutured; and it was doubtless true that hysterectomy might be performed more rapidly than hysterotomy and suture: the claim that there was no more shock following hysterectomy than usually attended the classical Cæsarean operation, the speaker was not prepared to admit. But in the absence of the above mentioned pathological conditions, which might necessitate

destructive surgery, was it justifiable, in performing Cæsarean section on either an elective or an absolute indication, to remove normal organs or to resort to other procedures with a view to preventing subsequent pregnancy, and the risk of a repeated section?

It was said that many women that came to Cæsarean section belonged to the depraved class, were often illegitimately pregnant, that they and their progeny were like lyto be a constant burden on the State. As sociologists we might well deplore modern efforts to promote the survival of the unfit.

But the speaker believed that the only safe and moral ground for the medical profession was that based on modern medical science, uninfluenced by sociological considerations. If a woman came to Cæsarean section and recovered, she and her husband, if she had one, should be informed of her condition and of the prognosis and treatment in the event of future pregnancy: if subsequent pregnancy ensued, the responsibility of treatment rested with the obstetric surgeon; but the responsibility for the condition rested elsewhere.

Dr. Whitridge Williams believed that a woman ought never to be sterilized in her first pregnancy, unless there was a distinct pathological indication. He did not believe in repeated Cæsarean section in the case of paupers. On the second pregnancy the patient should be sterilized. In a patient in the upper walks of life, the responsibility should, to a certain extent, be laid upon the patient. She should not be sterilized at the first operation, but this should be advised at the second.

Dr. Davis of Philadelphia said that from the standpoint of sociology, the woman and her husband had a right to demand sterilization. He had a patient with double hip-joint disease on whom he performed the operation.

Dr. Stone of Washington said that there were many times when there was no opportunity of performing Cæsarean section, and he suggested the induction of labor at eight months.

Dr. Fry of Washington believed in excision of the ends of the Fallopian tubes, when sterilization was indicated. He reported a case in which Cæsarean section had to be performed at term. Three weeks before he had seen the same patient, who, at that time, could have been delivered without this operation.

Dr. Jewett of Brooklyn said that sterilization was not so much in demand at present, on account of the success of Cæsarean section.

Renal Decapsulation for Puerperal Eclampsia.—Dr. Geo. M. Edebohls of New York read this paper. He said that renal decapsulation for puerperal eclampsia of renal origin was the logical outcome of the encouraging results following his operation in cases of chronic Bright's disease. He had successfully performed bilateral renal decapsulation for puerperal eclampsia upon a primipara two days after forced delivery. The convulsions began before labor and continued to the time of operation, the patient indeed having a convulsion while under chloroform on the operating table. This operation, performed on February 17, 1903, was believed to represent the first instance of renal decapsulation, or, for that matter, of any operation upon the kidney or kidneys, even undertaken for the cure of puerperal convulsions. The favorable results, immediate and remote, in this case, full details of which were given in this paper, at once assigned a place to renal decapsulation as one of the resources at our command in the treatment of puerperal eclampsia. A woman suffering from uræmic convulsions was entitled to the positive benefits of decapsulation whether pregnant, in labor or in the puerperium.

Dr. George Tucker Harrison of New York said that very few cases of puerperal eclampsia were of renal origin. Renal changes were secondary and not primary, but they existed, nevertheless, and he believed in giving this method a trial in desperate cases.

Dr. Philander A. Harris of Paterson said that little had been written about the subsequent history of renal troubles in eclampsia. The renal symptoms of exudative nephritis had been found to continue in many of the cases that had been traced.

Dr. Cragin said that the danger of the operation had to be considered. They had had only one death in twenty-nine cases of eclampsia at the Sloane Maternity Hospital. If the mortality of Dr. Edebohls's method was as low as that of the ordinary treatment it deserved to be tried.

Dr. Edebohls, in closing the discussion, said that those who were in a position to use this method could soon tell if it was valuable.

President's Address.—Dr. J. E. Janvrin of New York delivered this address, taking for his subject, "The Surgical Treatment of Early Diagnosed Cancer of the Uterus, More Especially by Hysterectomy." He first thanked the society for the honor they had conferred upon him. And he paid a tribute of respect to the memory of the three members who have recently died. In discussing the subject chosen for the theme of his paper, Dr. Janvrin first specified and pointed out the conditions in which vaginal or abdominal hysterectomy held out *good* hopes for a radical cure; he pointed out the conditions in which the operation held out *some* hope of a radical cure, and certainly a prolongation of life with a more comfortable existence than could possibly be hoped for if hysterectomy were not resorted to; and he described the conditions in which the operation should not be attempted—that is, with any hope of a cure. In his early operations, principally vaginal, like everyone else particularly interested in this subject, he made many operations with the hope of curing the patient, which a more extended experience soon showed should have been done simply with the idea of removing an extremely offensive organ, checking hemorrhage and the offensive discharge, and to prolonging life and making it more endurable. During the past fifteen years more care had been exercised in the selection of cases—fortunately more cases had been diagnosed while the disease was local and before any systemic infection had occurred—and, as a perfectly logical deduction, the percentage of ultimate cures had been more satisfactory. The speaker first took up the development of cancer in and from the cervix. After giving the statistics of various authorities, he quoted his own, which, up to January 1, 1899, were as follows: Abdominal and vagino-abdominal hysterectomies; twelve cases, two cured, more than eight years having elapsed. Six recurrences. Four deaths from operation (two from shock, one from septicæmia and one from anæmia). Percentage of cures, 16.6. Vaginal hysterectomies; thirty-eight cases, ten permanently cured. Fifteen recurrences. Four deaths from operation. Ten lost sight of after a few months. Percentage of cures, 26.3. Total number of cases, 50. Twelve cured. General percentage of cures, 24. According to Dr. George Gellhorn of St. Louis, "The fact had been brought out that in about one-third of all cases of uterine cancer involvement of the regional glands in the pelvis took place. This involvement, as a rule, occurred but very seldom in the incipient stage of the disease, but usually when the primary cancer had more or less advanced and extended into the parametria or other adjacent structures. Recurrence after the old methods took place in four-fifths of all cases in or near the cicatrix in the vagina, while it occurred in only one-fifth in the glands. Abdominal radical operation with removal of the pelvic glands was striving to lessen the high percentage of recurrences, but so far had not been able to attain the desired goal. This deficiency mainly depended upon anatomical and technical difficulties in routine ablation of pelvic glands. In a large number of cases this radical procedure, with its great and manifold dangers, had been found to be unnecessary, as there were no diseased glands anywhere within the pelvis. It had to be emphasized, however, that these conclusions were not as yet definite." The speaker be-

lieved that vaginal hysterectomy, with removal of as much parametrium as was possible by this method, and also the removal of the upper half-inch or more of the vagina, would accomplish just as much as any other method and, at the same time, carried with it the least danger as an operation *per se*, for it was extremely rare that a patient succumbed to this operation. It was by following out this rule that the statistics of the speaker's own cases, up to January, 1899, which he had already given, had been so favorable. During the past four years (since January, 1899) he had extended the field of operation, not with any idea of getting as good ultimate results, but simply for the purpose of removing a highly offensive local condition and, in that way, making a longer lease of life more comfortable to the patient and less offensive to herself and her friends. The use of the electric cautery clamp, as improved by Dr. A. J. Downes, theoretically should give the best results in this class of cases. No doubt it would do so as the technique of the operation became more familiar and the skill necessary for its application became greater in the hands of those who were making use of it. This would probably be especially true in cases in which the disease was locally somewhat advanced, too much so to be considered in its early stage and suitable for simple vaginal hysterectomy by the knife or the angiotribe; for the corking of the parts would leave a better protected surface against the immediate extension of the disease, and more than that, the fact, as shown by Dr. Gellhorn in his paper already quoted, that in a very large proportion of cases the lymphatics and glands were very slow to take up the disease, would become an additional factor in impelling us to make use of this method of procedure, not only in cases in which simple vaginal hysterectomy would necessarily be unpromising, but also in many instances in which abdominal hysterectomy, with attempts to enucleate the lymphatics and glands, had been thought to be justifiable. The speaker said that in presenting this paper, he was aware that the subject had been only partly covered, but his only object had been to so present it as to give (1) the conditions under which hysterectomy should *always* be done for cancer of the uterus, leaving it a matter of choice to each individual operator as to whether he selected the vaginal or abdominal or the combined vaginoabdominal route; and at the same time to fortify this position with sufficient statistics, at home and abroad, to make the position tenable, and to impress upon the profession at large the absolute necessity of recognizing the early symptoms, and then seeking the advice and assistance of some surgeon who had had a good amount of experience in these cases, so that the hysterectomy could be done when it ought to be done. (2) To describe another class of cases in which any operation, no matter how radical, would in a large majority of cases fail to give permanent relief; but to state his entire approbation of it in the hands of expert operators. For it was only by continuous work and the accumulation of the statistics in these major operations at the hands of master operators that we could finally come to a definite understanding as to what we could accomplish and what we could not accomplish in the surgical treatment of cancer of the uterus.

Carcinoma of the Cervix Uteri.—Dr. Thaddeus A. Reamy of Cincinnati gave the history of several cases of this nature He said that spontaneous recovery from carcinoma did not occur. Unequivocal recovery, lasting for ten to twenty-five years, of even two cases following removal of the diseased and adjacent tissues, proved the curability of carcinoma of the cervix, and its local origin. He quoted no authorities, as he wished to prove from his own work that in some cases, when operated on early, cure followed removal of diseased tissue. He made no point as to the method of operation. In most of the cases quoted the operation was simply amputation of the cervix. Comparison of methods was not his present purpose. No treatment could be of any permanent avail unless instituted in the very earliest stages of the disease, before there was any general lymphatic involvement. In most, if not all cases of epithelioma of the cervix, several weeks, indeed months, elapsed before glandular involvement or extension from the point of attack. During this stage was the time for operation, and if done during this stage a cure might be expected in a good per cent. of cases. If the operation were made at this stage it was doubtful whether anything could be gained by removal of the uterus. He urged that the family physician should watch with greater zeal and more care than ever in the past for the first manifestations of the disease. He should not wait for the patient to ask him why she had a "bloody show" at irregular times, but should make it his duty to put every married woman over thirty years in families under his care on her guard, explaining to her fully first symptoms and the importance of communicating them. And in any suspicious case the family physician should insist upon an examination.

Primary Carcinoma of the Vulva.—Dr. Reuben Peterson of Ann Arbor reported the history of four cases of primary carcinoma of the vulva. Although it was generally acknowledged that carcinoma of the vulva was a rare disease, still statistics showed that it was more frequent than was generally supposed. Guret estimated that in 10 per cent. of all cases of carcinoma in the female, the seat of the disease was the vulva. It was difficult to reconcile this estimate with the experiences of some of our American gynecologists. There seemed to be a predisposition for carcinoma of the vulva to attack old women. The average age was higher than with carcinoma of other parts of the genital tract. In the speaker's series, the ages were distributed between two decades, forty to fifty and fifty to sixty. The youngest was forty-three and the oldest eighty-four. The location of the growth was practically the same in three of the cases reported, viz., to the left or right of the clitoris and a little below that organ. The urinary meatus was rarely the seat of the primary disease. In three of these cases intense pruritus was the first symptom of any importance. One case reported represented the active form of the disease. A few months after its appearance on the left labium majus, the growth had ulcerated and spread to the clitoris and had involved the inguinal glands early, as the disease recurred there after the radical removal of the growth. The cells were actively proliferating. For the most part there was no tendency toward cornification. Another case was of the opposite type. The patient had had the disease for some seventeen months and while extensive, locally, the inguinal glands were not enlarged. Microscopically, it was a typical squamous celled-sarcoma, with a marked tendency toward the formation of epithelial pearls and cornification. Careful serial sections of the inguinal glands failed to reveal any evidence of cancer. The speaker believed that it would depend largely upon the type of the particular growth under consideration whether we might expect involvement of the inguinal glands. The difficulty lay in our inability to determine in what particular case the disease had not spread by way of the lymphatics; hence, as in cancer of the breast, we were driven to the removal of the inguinal glands, whenever we aimed at a radical cure. The glands should be removed first to avoid contamination of the operative field. The glands in both inguinal regions should be removed, because it was impossible to state positively that the disease had not involved the opposite side of the vulvar cleft. If carcinoma of the vulva could be seen and treated early enough, good results could be obtained. Veit quoted Schwartz as having ten permanent recoveries out of twenty-three cases. While this might be overstating the case somewhat, it was unquestionably true that there was much more hope of cure in carcinoma of the vulva after the radical operation, than after the most radical operations for carcinoma of the uterus. The speaker passed around photographs of his cases.

Dr. J. Riddle Goffe showed some photographs of a pseudo-hermaphrodite upon whom he had operated with good results.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Paroxysmal Tachycardia of an Epileptic Nature.—Gaetano Bellisari states in conclusion of his article: (1) That there exists a variety of paroxysmal tachycardia which must be considered as epileptic. It may originate, like ordinary epilepsy, from a neurotic heredity, trauma, or cortical foci. (2) During the attack this form of the disease offers no symptoms different from the so-called essential tachycardia. (3) Diagnosis should be based on the anamnesis, the nocturnal onset, the preceding or consecutive phenomena, and the influence of bromide treatment. (4) The attacks may be considered as a condition of arrest of the cardioinhibitory function of the vagus due to irritation of the cortex. (5) Prognosis, as a rule, does not need to be as reserved as in other cases. (6) Frequency of attacks, however, may lead to permanent hyposystolie; but in such a case it is not possible to absolutely exclude the existence of an anatomical lesion of the myocardium, independent of the neurosis.—*La Riforma Medica.*

Conjunctivitis as the Result of Fast Riding in Automobiles.—A. Edward Davis says that the three characteristic symptoms of this disease are: (1) Congestion of the ocular conjunctiva almost solely; (2) the deeper conjunctival and sub-conjunctival tissue being markedly affected; and (3) a slight watery discharge attended with but little itching and burning. The indications for treatment are simple. Prohibit the patient from riding in open automobiles, or else have the eyes well protected by a close-fitting pair of goggles. The local treatment consists in the application of cold compresses to the eye, for fifteen minutes at a time, three or four times a day, and the application of mild astringent washes by means of an eye cup twice a day. In cases in which latent and chronic inflammations in the deeper tissues of the eyes have been made active, riding in the open is to be strictly prohibited, active use of the eyes for close work discontinued, and appropriate treatment instituted after examination by an oculist. The author wishes to protest against the indiscriminate use of adrenalin chlorid solution. Its continued use is often positively harmful.—*The Post-Graduate.*

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending May 30, 1903:

	Cases.	Deaths.
Measles	356	13
Diphtheria and croup	378	42
Scarlet fever	246	14
Smallpox	3	..
Varicella	71	..
Tuberculosis	205	144
Typhoid fever	42	10
Cerebrospinal meningitis	..	9

Primary Tuberculosis of the Breast.—W. S. Schley reports one case, and gives an elaborate review of the literature of the subject. His patient was a woman of thirty-two years. Family history was negative and she had nursed five children without any mammary trouble. Eight weeks before admission to hospital pain was felt in the right breast, followed three weeks later by a small lump in the upper and outer quadrant. Two weeks before admission it began to grow rapidly and became very painful. Chest examination was negative. The lump was not tender. skin was not adherent. The breast was amputated and the axilla cleared out. The breast was filled with a soft mass, from which radiated connective tissue strands. The growth closely resembled a scirrhous carcinoma. Under the microscope a moderate amount of adenomatous tissue was visible. There was also abundant infiltration of the connective tissue with small round cells, and in places distinct tubercles with giant cells and central necrosis. The whole of the tumor was diffusely infiltrated with these evidences of tuberculosis, but there were no large cheesy masses and no other evidences of tuberculosis than those given above. The tubercle bacilli were demonstrated in stained sections of the tumor. The axillary lymph nodes were perfectly normal. Two weeks after the operation the patient was given an injection of seven milligrams of tuberculin, but showed no reaction. As a control to this test, three other known cases of surgical tuberculosis were given each six milligrams from the same dilution and gave typical reaction.—*Annals of Surgery*, April, 1903.

The Treatment of Typhoid Fever with Benzoyl-Acetyl-Peroxide, or Acetozone.—Frederick G. Harris says that many patients were given acetozone, but with much irregularity on account of many contributory causes; dislike of the odor and taste of the solution; resistance of ignorant patients; lack of persistence on the part of overworked attendants, due to crowded wards caused by the epidemic. Those patients who are given the drug early, often, and regularly show the best results of this treatment. What Virchow calls the "brutal force of figures," cannot but convince anyone that acetozone lowers the temperature, shortens the duration of the fever, and lessens its toxic symptoms more than our better known treatments. From the information gained in watching a series of one hundred and twenty-eight cases of typhoid fever, the author believes that when the cases can be seen during the first week of the illness, and given large amounts of acetozone solution regularly and often, assisted by a gentle laxative, the temperature will return to normal in from ten to twelve days.—*The Therapeutic Gazette*, March 15, 1903.

Some Developments in Anæsthetics.—W. J. McCardie remarks that he has given ethyl chloride to more than 400 patients, and has never had the slightest anxiety during the administration. The after effects are usually slight or absent, though there is some tendency to vomiting. It can be used with advantage in short operations lasting ten to fifteen minutes, instead of ether or chloroform, and sometimes is much better than nitrous oxide. Its use, by those who are not experts, is not advised in adenoid operations. It is practically impossible to give nitrous oxide satisfactorily for any operation lasting more than a quarter of a minute in the mouth of small children. Not only do they become cyanosed, and bleed to such an extent that it is almost impossible to see what one is trying to do, but convulsions of the limbs and body are very awkward, and recovery exceedingly rapid. With ethyl chloride, however, there are none of these disadvantages. —*Treatment.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending May 23, 1903:

SMALLPOX—UNITED STATES.]

ON NEUROFIBROMATOSIS.*

BY DR. JOSEPH FRAENKEL,

INSTRUCTOR IN NERVOUS DISEASES CORNELL UNIVERSITY MEDICAL COLLEGE; ATTENDING PHYSICIAN TO MONTEFIORE HOME;

AND

DR. J. RAMSAY HUNT,

INSTRUCTOR IN NEUROPATHOLOGY IN CORNELL UNIVERSITY MEDICAL COLLEGE; NEUROLOGIST TO CITY HOSPITAL; ASSISTANT PHYSICIAN TO MONTEFIORE HOME.

GENERAL neurofibromatosis is, according to Virchow, a rather unusual condition. When this statement was made in 1863 there were thirty cases in literature. In a clinical lecture on neurofibromatosis Marie remarks that "Without being rare, it is hardly known by name."

One of the cases we are about to report, and which at the autopsy gave an unexpected finding, was incorrectly diagnosed in life not so much on account of diagnostic difficulties, as that neurofibromatosis was not thought of.

Neurofibromatosis is the formation of one or more tumors in one or more cerebrospinal or sympathetic nerves.

Tumefactions are encountered, varying in size from a bead to a child's head. In some cases the manifestation of the disease is expressed by a solitary growth upon one nerve, and in other cases almost innumerable growths have been present, as in a remarkable case of Pruddens, in which over 1,000 tumors were counted.

They occur on all cerebrospinal and sympathetic nerves except on the optic and the olfactory.† These nerves are essentially outgrowths of the brain, and consequently their supporting structures are made up of glia tissue. The acoustic nerve, which by older writers was supposed also to possess the mentioned immunity, has been shown by later investigation to be particularly liable to the formation of fibromata and fibrosarcomata.

The origin of these tumors is usually from the endoneurium, rarely from the perineurium and exceptionally from the epineurium. These tumors are situated either centrally within the nerve (endoneural variety) or eccentrically on the periphery of the nerve (epineural variety).

The general conformation of the tumors is spherical or elliptical and in generalized cases the nodular outgrowths give the nerve a convoluted appearance, sometimes resembling a rosary.

Histologically, the fibroma nervorum is made up of connective tissue elements, which present all the variations in structure between the fibroma molle and the fibroma durum. The majority of these growths contain a considerable interfibrillary œdema. The individual fibro-blasts or coarse bands of connective tissue, as the case may be, are widely separated by a homogeneous substance which remains unstained.

There are other enlargements occurring on cerebrospinal and sympathetic nerves which bear a superficial resemblance to neurofibromata: (lepra-nodules, gummata, sarcomata, and tuberculous nodules) but a careful inspection will usually, and a microscopic examination always separate these conditions from the one under discussion.

The true neuroma, which is due to a proliferation of nerve elements, nerve fibers, medullated or non-medullated, is to be kept sharply defined from the class of tumors under discussion. Although in rare cases, some observers have thought that the nerve elements have taken part in the proliferation even in this latter class. An illustration of the occurrence of both, fibrous and neural proliferation, is found in the familiar amputation-neuroma.

The neurofibromata are slowly growing tumors of a benign nature. Frequently, however, they undergo a retrograde metamorphosis and show cystic, fatty, or myxomatous degeneration. In some instances these tumors undergo sarcomatous transformation, assuming a malignant character, giving rarely metastases, as in cases reported by Westphal, Recklinghausen, and Larkin. According to some observers, this is not actually a sarcomatous transformation, but a growth with primary sarcomatous tendencies.

The manifestation of general neurofibromatosis is not confined to the cerebrospinal and sympathetic nerve trunks. The multiple fibromata of the skin are fibromata of the terminal filaments of cutaneous nerves, as demonstrated by Recklinghausen. In many of these tumors, however, Recklinghausen further showed a connection with the connective tissue capsule of the sudoriferous and sebaceous glands. Still another and important manifestation is the so-called plexiforme neuroma or pachydermatocele of Valentine Mott. This in a more diffuse form produces the elephantiasis neuromatodes.

All expressions of the neurofibromatosis have been proven in many instances to be hereditary; in a still larger number of cases the congenital origin has been demonstrated. It has further been clinically ascertained that neurofibromatosis is frequently associated with more or less mental impairment, imbecility, and somatic stigmata of degeneracy. Scrofulosis and tuberculosis are often found in the histories of cases of neurofibromatosis. All this suggests the teratological nature of the disease. In one of our cases, homosexual impulses were a feature of degeneracy.

From the foregoing it is apparent that the mentioned variety of size and position of the tumors will produce considerable diversity of clinical phenomena.

Clinically, cases of neurofibromatosis can be divided into those with and those without symptoms. It is a well-established fact that neurofibromata have been found at the autopsy without having been suspected at all during life, and frequently cases are observed presenting numerous nerve

*From the Montefiore Home and the Pathological Laboratory of the Cornell University Medical College. Read before the American Neurological Association, June, 1902.

†Carl Emanuel-Graef's *Archiv für Ophthalmologie*, Lill, 1901, attempts to establish a relationship between general neurofibromatosis and elephantiasis neuromatodes and the so-called gliomata of the optics.

tumors without any symptoms referable to this lesion. Neurofibromatosis may present itself clinically in one of the following ways: (1) Tubercula dolorosa (painful tubercles, Wood); (2) multiple neurofibromata of the skin (molluscum fibrosum, Recklinghausen's Disease); (3) neuromata [cranial or spinal] or neurofibromata of a single peripheral nerve; (4) neuroma plexiforme, pachydermatocele, and elephantiasis neuromatodes; (5) generalized neurofibromatosis; neurofibromata of the skin, cerebrospinal and sympathetic nerves.

The tubercula dolorosa are characterized by the appearance of small, very painful cutaneous nodules. They arise apparently from the sensory skin filaments and may occasion paræsthesias, contractures, reflex spasms, and, according to good authority, even epileptiform seizures.

The multiple neurofibroma of the skin is a dermatologically well-known condition. The disease is apparently congenital, occurring mostly in dwarfish, undersized people of somewhat impaired intellectual capacity. It is characterized clinically by numerous (several hundred) cutaneous nodules of all sizes (from a pin's head to a goose's egg). These tumors are sessile and usually not painful. They give rise to no symptoms when existing on the skin only. Frequently, however, in addition to the skin phenomena there are endo- or epineural fibromata present, and these condition symptoms according to size and situation, although not necessarily so at all times.

Neurofibromata of individual peripheral nerves (isolated neuromata) are surgically well known. They express themselves clinically by paræsthesias and progressive motor weakness of the peripheral nerve type, and are of good prognosis when recognized. They occur most frequently on the median and sciatic nerves; they are rarely without symptoms and are prone to give rise to considerable hyperæsthesias and little paralysis.

Neuroma plexiforme, pachydermatocele and neuromatous elephantiasis are clinical curiosities, and are more of dermatological and surgical than of neurological interest. Their neurological importance consists mostly in the fact that their presence occasionally may give suggestion, and lend aid to the diagnostic interpretation of obscure neural symptoms.

The generalized neurofibromatosis of the skin and cerebrospinal and sympathetic nerves is apparently the rarest of all enumerated types and the basis of exceptional and unique clinical pictures.

All of the above-mentioned types are expressions of the same pathological tendency. Atypical and unusual syndromes are occasionally found explained by multiple neurofibromatosis: attacks of neuralgia paræsthesias, reflex spasms, contractures, mono- para- quadruplegias. One case recently published by Marie showed during life progressive mental degeneration and curiously localized osteomalacia of the thoracic skeleton. The post-mortem explanation was found in a large number of neurofibromata on the duodenum, jejunum, and ilium. One of the cases we are about to describe presented itself under the clinical picture of compression myelitis.

It is well to state here, that sometimes the general picture of the disease may be entirely masked by the occurrence of a tumor within the cranial cavity or vertebral canal, causing the classical symptoms of tumor in these localities. Some writers have separated the latter group—particularly the intracranial group—under the name of "Central Neurofibromatosis."

Little is known thus far of the etiology of the condition. An hereditary influence is undoubtedly established in a number of cases; a large number is left, however, without satisfactory etiological explanation. Traumatisms to the nerves are of indisputable value, as is best evidenced in the familiar form of amputation neuromata. Arsenical intoxication has been observed to be followed by formation of neuromata. The etiological rôle of infections is very problematical. Marie lays stress on this point and one of our cases followed an attack of typhoid fever.

The diagnosis is, when the condition is thought of, obviously a very easy one, and has to be differentiated from multiple lipomatosis of the skin, the so-called molluscum pendulum, and from another condition only lately brought to the notice of the neurologist, the symmetrical cervical-adeno-lipomatosis.

Aside from the palpatory impression and the distribution and relation to the nerves, the neurofibromatous nodules are more prone to be sessile, while lipomata are more often pedunculated.

Fig. I.

The symmetrical adeno-lipomatosis is characterized by the very distinct symmetrical distribution of the tumefactions, by their usually larger size, their gelatinous consistency and their predominant frequency around the cephalic extremity; whereas the generalized neurofibromatosis is, as a rule, less commonly situated here, with the exception of the neuroma plexiforme occurring on the trigeminus.

The pathological kinship between neurofibromatosis and all kinds of nævi (nævus vasculosus-pigmentosus-pilaris), which, according to some authors, are the expression of the earlier stages of neurofibromatosis, makes their presence speak in favor of neurofibromatosis. Finally, Dercum's dis-

ease, some forms of leprosy and curious varieties of thyroidism (Langhans) must be borne in mind in differential diagnostic considerations.

From a therapeutic and prognostic standpoint, the epineural variety is regarded more favorable than the endoneural, as the former can be detached without much damage to the nerve, while the endoneural variety, if therapeutically handled, will more frequently necessitate resection of the nerve and lead to lasting structural damage. The appearance of symptoms in a previously latent case, may prove of prognostic import, denoting sarcomatous change within the tumor.

Since the writer's attention was first called to the subject, they have been able to examine four cases representing the three principal groups of this condition.

Case I (Compression myelitis produced by intervertebral fibroma). — R. K., twenty-six years old, female, born in Russia, a machine operator, married, was admitted to the Montefiore Home on January 4, 1892. It was only in '97 that the patient came under the direct observation of one of the writers, and at that time the following history and status were taken:

Fig. III.

Fig. II.

Patient was, at date of examination, June, '97, thirty-one years old, and complained about extensive motor paralysis of upper and lower extremities, about frequent and annoying attacks of muscular twitchings and painful muscular cramps, about some difficulty with respiration, obstinate constipation, and hurried action of the sphincters.

Family history is apparently negative.

Previous Personal History: Was born at full term. Had the usual children's diseases. When eight years old had malarial fever. Began to menstruate at twenty-two. Was married at twenty. Had one still-born child. No history of venereal infection was obtained.

The present disease began eight years ago after birth of child. The cause of the disease was unknown to the patient. Patient went to the Mt. Sinai Hospital, and was there treated for nine months with strychnine injections and electricity. She left the hospital unimproved.

Some time later slowly progressing loss of motor power of right lower extremity appeared; this was not preceded by pain. Simultaneously with the beginning of the disease, the tumefaction of the left abdominal wall (to be described later) appeared. Patient is emphatic about this fact. At this time patient entered the Montefiore Home, and began then to have occasional not very sharp pain in the back. During patient's stay at the Montefiore Home different diagnoses were made. An hysterical nature of the condition was strongly suspected and the patient was treated accordingly.

Marked and obstinate contractures of the lower extremities developed. Tenotomies were made and the lower extremities were put up in plaster of Paris. These procedures proved very unsuccessful and added a good deal to patient's discomfort. They were then abandoned.

After this, slight sphincteric disturbances appeared. There was no genuine incontinence of rectum or bladder, but the disturbance was principally one of insufficiency.

About the same time patient noticed progressive emaciation of the hands and lower ends of the forearms, and began to be annoyed by muscular twitchings and severe painful spasms. These phenomena could be controlled only by absolute motor quietude and the patient's assuming a certain position.

Status: Patient is unusually short, darkly pigmented, without somatic signs of degeneracy.

The adipose tissue is very abundant, particularly around the abdomen. Temperature 97°, pulse 72, of good volume and tension. Respiration 28, somewhat labored.

Examination of the vegetative organs negative.

The most comfortable attitude for the patient is the following: The upper part of body elevated. Upper extremities crossed over chest. Lower extremities flexed in hip and knee-joints.

In the skin of the right lower abdomen there is a large baggy mass. This mass is soft, freely movable, not tender. The skin over it shows a dark reddish discoloration. On palpitation it conveys the impression of a bunch of small hard beads. Otherwise no scars or other noteworthy features on skin. On buttocks small benign-looking decubital ulcers. Upper extremities are tapering, main en griffe, much more marked on left than on right side. Both feet are in position of equino-varus.

A general muscular restlessness is noteworthy. This restlessness is best described as choreic, and is observed on upper extremities as well as on lower. These twitchings are not influenced by the will or attention, and are apparently controlled by the

patient assuming the position described above, *i.e.* extreme flexion in all joints of the extremities. These mild facicular and painless twitchings are occasionally interrupted by severer painful spasms of different muscle groups.

There is a localized and marked hyperidrosis of the face. Left palpebral fissure is much smaller than the right. Pupils slightly serrated, dancing, equal on both sides. Light, consensual, accommodation and pain reactions are prompt. Ocular excursions are normal. Optic nerves without findings. Vision normal. No limitations of field.

Fig. IV.

Smell, taste, and hearing unimpaired. Slight physiological asymmetry of facial innervation. Sensibility of face and head unimpaired. Excursions of head not painful. Jaw-jerk very lively.

Patient is unable to sit up without assistance. Respiration predominently diaphragmatic. Considerably impaired action of intercostals. Back muscles decidedly weak. The vertebral column shows normal configuration, not tender anywhere to pressure, not sensitive to jarring from above or below.

Considerable motor paralysis of upper extremities, particularly of muscles of hands, fingers, and wrists. No resistance to passive movements of upper extremities, no ataxia, tremor, or incoördination.

The tactile, pain and temperature (Fig. XI) senses were changed on ulnar side (see diagram). Kinesthetic sense of upper extremities undisturbed. No reflexes elicitable on upper extremities. Considerable resistance to passive movements of lower extremities, more to extension than to flexion. Total motor paralysis of both lower extremities. Frequent and vigorous motor spasms. Lower extremities somewhat tapering nowhere individual atrophies seen.

The examination of the knee-jerks was quite difficult, owing to the frequent involuntary contractions of the muscles. With much caution and care, however, the following was established: (1) The presence of a crossed adductor jerk; (2) the variability of the knee-jerk; (3) the fact that the knee-jerks were not exaggerated.

The Achilles jerk was at no time obtainable (perhaps masked by contracture). Plantar reflexes prompt. Total sensory paralysis of lower extremities and trunk, as shown in diagram. The kinesthetic sense mostly altered in toe and ankle-joints. The electrical examination showed a quantitive diminution of the excitability of the extensors of the wrist and most of the intrinsic hand muscles.

The ulnar, median, and radial nerves gave normal reactions, with the exception of the left-sided ulnar, where the reaction was sluggish and showed polar changes. Muscles and nerves of lower extremities

Fig. V.

did not respond to any electrical stimulation (contracture).

The patient was examined quite frequently and seen by a number of physicians and no definite diagnosis was reached. A neurofibromatosis was at no time thought of. The presence of above-mentioned skin tumor was looked upon as a simple birth-mark.

Little change was observed in patient during the next three years. Another examination was then made, principally with the object in view to gain sufficient justification for an eventual operative interference. This second examination brought no further facts to light, and so the patient was left to her fate and the conception of her condition was no clearer.

The fact of absence of severe shooting root pain during the whole course of the disease, was the main reason for the decision against an operation. From then until January, 1902, when patient died, few new symptoms developed, excepting the usual final stages of chronic transverse lesions of the cord.

Fever and progressive emaciation developed in consequence of a purulent cystitis. During the last few months patient suffered considerably from embarrassed respiration. A few months before death, a firm tumefaction the size of an egg de-

veloped in one of the intercostal spaces of right side.

Autopsy.—The autopsy of the thoracic and abdominal viscera proved negative, with the exception of a chronic cystitis and hypostatic pneumonia. The examination of the brain and meninges presented no variation from the normal. The cranial

Fig. VI.

nerves within the skull were normal in appearance. On the left vagus just above the jugular foramen a small nodule was noted. On opening the spinal canal a firm growth appeared beneath the seventh and eighth cervical and the first dorsal vertebræ. This tumor projected posteriorly and completely concealed the cord. It was attached to and beneath the dura. After its removal the flat-ribbon-like remnant of cord came in view, gradually tapering to the normal cord contour. (Fig. I.)

The tumor was one and one-half inches in length, inch wide and 1 inch deep, of prismatic contour, accurately moulded to the interlaminar space. Attached to the under surface of the tumor was a thread-like prolongation which had been torn from its attachment to the cord on removal. The anterior and posterior roots of the cervical cord were enlarged either diffusely or presenting nodular outgrowths and fusiform swellings.

Most of the spinal ganglia of this region were distinctly enlarged. The dorsal and lumbar roots were found normal. A few thoracic spinal ganglia were enlarged. The cauda equina presented macroscopically a normal appearance.

The cervical and lumbar plexuses presented the classical picture of the neuroma plexiforme. (Fig. II.) The uniformly greatly thickened nerve-trunks were fused into a massive network with occasional nodules and tumefactions. Attached to the right lumbar plexus was a tumor the size of a goose's egg. The brachial, crural, and sciatic nerves which were examined in a part of their course presented evidences of neurofibromatous thickening.

There were no larger tumefactions on any of the peripheral nerves, excepting one, the size of a hen's egg on the right sixth intercostal nerve.

Both vagi, in their cervical and thoracic course, were the seat of diffuse varicose thickening. (Fig. III.) The cervical, thoracic, and lumbar sympathetics were normal in appearance.

The tumor of the left lower abdominal wall was a plexiforme neuroma of the skin. In addition to the elephantiasis-like thickening of the skin and subcutaneous tissues, an intricate interlacement of fibrous cords was seen on transsection. Here and there were local nodulations. An abstract of the histological examination is as follows:

All cranial nerves, excepting those of special sense, were subjected to microscopic examination. No fibrous thickening was noted. The small nodule on the left vagus was a neurofibroma; it contained a few ganglion cells, apparently belonging to the ganglion jugulare vagi.

The cord tumor was a fibromatous structure without demonstrable nerve fibers. The dura mater was adherent posteriorly. The atrophic nerve fiber

Fig. VII.

adherent to the capsule consisted of connective tissue and blood vessels without neural elements.

The swelling of cervical and lumbar roots and the mentioned thickening of spinal ganglia were produced by a fibromatosis. In the cauda equina and the spinal roots, which appeared macroscopically normal, scattered islets of fibrous tissues were demonstrated. (Fig. IV.)

At the site of the greatest compression of the cord only a few nerve fibers remained intact. (Fig. V.) The ganglion cells are represented by calcareous remnants. The spinal arteries were not obliterated. Strictly speaking, the lesion was incomplete. There were the customary ascending and descending degenerations noted. Unusual was a retrograde atrophy of the pyramidal tract, which up to the present time was traced to the decussation.

Fig. VIII.

In the peripheral nerves the following peculiarities were noted: (Figs. VI and VII) (1) Proliferation of the endoneurium alone, most commonly; (2) a concentric thickening of the perineurium; (3) a combination of endo and perineurial proliferation; (4) in the most advanced stages the epineurium was found diseased also, leading to fusion and deformity of the nerve-trunks; (5) the varicosities and tumefactions were found to be histological expressions of a local aggravation of any of the just enumerated types of hyperplastic tendency. Here the tissue is of a more embryonal character, resembling a fibroma molluscum.

In the peripheral nerves the endoneurial and perineurial proliferation is the rule. In the plexuses the process presents the advanced stage implicating the epineurium. The nerve fibers are generally found well preserved, even where there is considerable proliferation. Occasionally they are slightly diminished in number, at no time totally absent. Even where the myelin sheath has been destroyed, naked axis cylinders were observed. Many Mastzellen of Ehrlich or Waldeyer's plasma cells were encountered.

The neurofibromatous character of the skin tumor was proven by histological examination. The connection of the nodules with dermal nerves was demonstrated in some, in others the proof was wanting.

Case II.—(Isolated neuromata of the posterior tibial and communicans-peroneii nerves. Hyperæsthesia, paralysis, operation, recovery.)

S. K., a female, eighteen years old, born in Russia, single, was admitted to the Montefiore Home on May 17, 1895.

Family History.—Father died suddenly from heart disease at forty-six. One brother had heart disease. Patient was born at full term, was a healthy child, began to menstruate at fifteen, was free from disease until five months ago. Then developed typhoid fever, for which she was treated at the Beth Israel Hospital. While there the patient experienced pain, localized in right ankle-joint. This joint could not be moved at all without pain. The toes could at that time be moved freely, but even without using the joint, patient experienced attacks of sharp neuralgic pain in joint, and same was excessively tender to the slightest touch.

One month later the right leg began to grow thinner, and slowly the foot assumed the position of equino-varus. Heat mitigated the pain considerably, and cold applications proved unendurable. Some time later the pain spread from the ankle-joint upward to the knee.

At time of admission patient complained about inability to walk, owing to pain in right lower extremity, distressing and restless sleep, poor appetite, constipation, shooting pain all over body, particularly in right leg, although not so severe as formerly.

Examination.—Patient is well built, nourished, small, darkly pigmented, without physical signs of degeneracy. Pulse, 96; temperature, 100°;

Fig. IX.

respiration, 30. With the exception of evidences of a well-compensated mitral insufficiency, the visceral organs were normal.

Over skin of both fore-arms a few hypertrophied keloid scars were noted, the result of hypodermic injections. In both lower extremities, small, round subcutaneously situated nodules were found. They were situated on the posterior surface of the extremities. They varied in size from a pea to a small nut, and were tender to pressure, more on right than on left side.

Most of the nodules did not seem to have any

connection with particular nerves, with the exception of one situated behind the head of the fibula in the course of the peroneal nerve, and another one, situated on the posterior part of the right leg at about the junction of the upper and middle thirds, corresponding to the course of the communicans peroneii. The last-named two tumors were about the size of a cherry, and quite tender to pressure. The skin over the nodules was freely movable. The nodules themselves, however, could not be moved in a horizontal or vertical direction.

Excursions of head and eyes are normal. Pupils normal. Motor and sensory portions of trigeminus

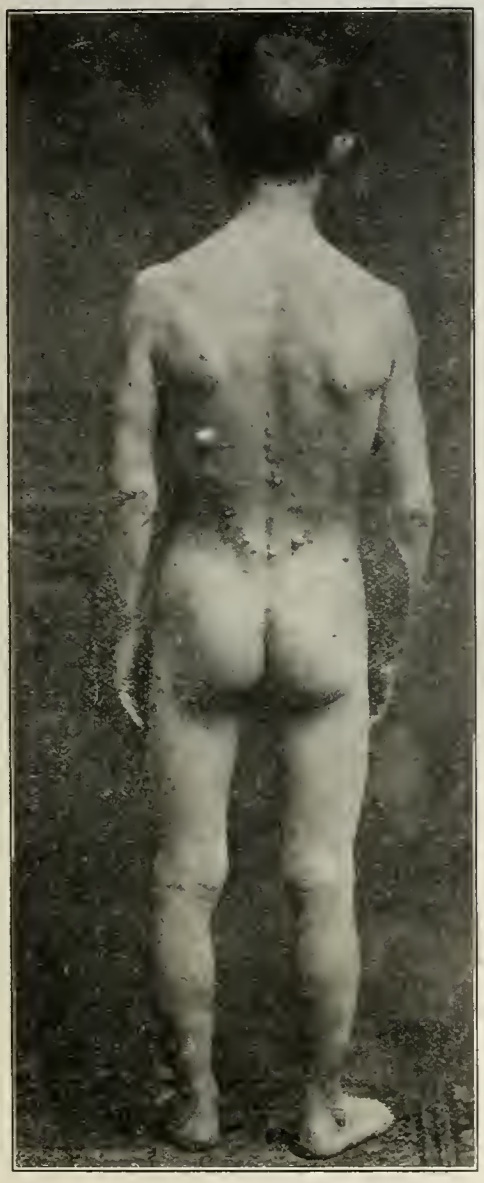

Fig. V.

and special senses normal. Motility of upper extremities normal. Right upper extremity a trifle weaker than left. Reflexes, coördination, and electrical reactions of upper extremities normal. Left lower extremity normal. Right lower extremity much thinner than left.

Beginning at the knee, the emaciation of right leg is very marked. Pes equino-varus and considerable flexion-contracture of toes. Motility of hip and knee-joints normal. Active excursions of ankle and toes almost nil. Sensibility down to level of ankle-joint normal. Whole foot excessively hyperæsthetic to slightest touch, with the exception of skin over metatarsus hallucis and second toes where the sensation is considerably dulled. (Fig. VIII.)

The right sciatic, peroneus and tibial nerves are very tender to pressure. The electrical examination showed considerable quantitative diminution of direct excitability of upper portions of soleus and gastrocnemius muscles, the other nerves and muscles of right leg do not respond to any electrical stimulation.

It was evident that the symptoms of the right lower extremity were due to the nodules. It was decided to remove the one most clearly responsible for the symptoms, *i.e.* the one corresponding to the course of the communicans peroneii; this was removed under local anæsthesia and found to be loosely connected with the subcutaneous tissue and in no apparent connection with any nerve. The nodule was as big as a hazelnut and contained fluid. After the operation the hyperæsthesia became markedly lessened, although not sufficiently to enable the patient to use the foot.

Two months later another operation was made by Dr. George R. Elliott in order to remove the other nodule, the one behind the head of the fibula. At this second operation search was made on the sciatic up to middle of the thigh and down to the sciatic bifurcation, for other fibromata; none were found. The result of the second operation was much more gratifying than the first. The hyperæsthesia disappeared to a large extent and the contracture diminished. Six weeks later a right-sided achilio-tenotomy was made and the right foot put in plaster of Paris. Four weeks later patient was fitted with a proper shoe, and improved so far that she could soon be discharged from the institution.

At present patient is free from pain and working. The present condition shows still these symptoms: General atrophy of the muscles, equino-varus contracture, no electrical response of the muscles supplied by anterior tibial nerve, slightly dulled pain sensation of outer surface of leg, no nodules demonstrable at present.

On microscopic examination it was found that the center of the nodules had undergone cystic degeneration. The margin showed a rather dense fibrous tissue, in which numerous nerve fibers were demonstrated by the Weigert method.

Case III.—Type of Recklinghausen's Disease. Fibromata of peripheral nerves. No symptoms. (Figs. IX and X.)

H. Z., thirty-six years old, Hungarian, married, tinsmith, was admitted to the Montefiore Home November 4, 1901, for extensive, probably tuberculous chronic bronchitis.

Family History.—Father died from unknown cause. Mother died from tuberculosis. There were seven children in family. One died from tuberculosis, the others are well. There is no similar skin trouble in the family.

Previous Personal History.—Patient was born naturally; had measles when a child; remained the shortest of the whole family; was a moderate man; denies venereal infection; his wife gave birth to three healthy children, and miscarried four times.

Present disease began two years ago with a hæmoptosis and loss of weight. Patient showed the usual physical signs of chronic pulmonary tuberculosis. Patient noticed skin trouble as long as he can remember. It never annoyed him much excepting a few years ago, when one of the tumefactions grew to the size of an apple. This was removed.

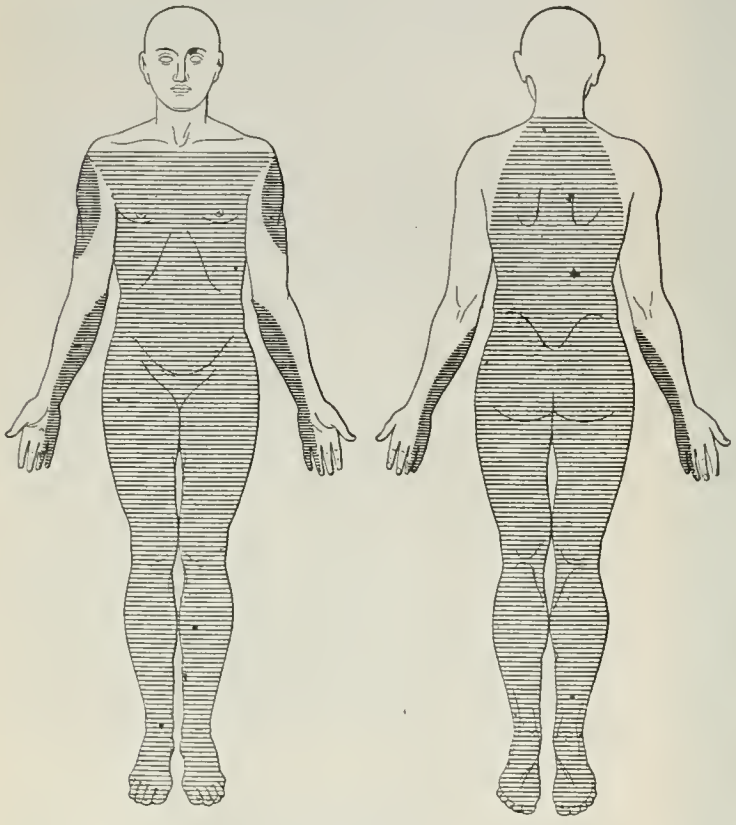
In addition to the symptoms referable to the pulmonary condition, the patient complained about

attacks of vomiting. These attacks were apparently independent of the time when food was taken, or of the quality of the latter, for the vomiting occurred without warning or any disagreeable sensations.

The expulsion of the contents of the stomach was followed during these attacks by a discharge of a considerable quantity of peculiarly viscid fluid. Patient further complained of attacks of somnolence and general weakness and exhaustibility.

Patient is four feet nine inches in height, weighs 87½ pounds. Head rather large, being 22¾ inches in circumference. Pupils somewhat unequal, the left a trifle wider. Skin is covered by a number of cutaneous tumefactions which vary in size from a pea to a walnut. Interspersed between these tumefactions are small vascular nævi. These tumefactions are densely strewn over chest and abdomen, much less on extremities, none on head, a few on chin.

In the left intercostal space is felt one larger tumefaction the size of a plum. About four



Diagram—Fig. XI.

tumefactions, the size of cherries, are felt in the cervical plexus, and a few similar ones in both brachial nerves. These tumefactions are sensitive. The ones situated in skin are freely movable with the latter. Those situated in cervical plexus and brachial nerves show no excursions in vertical, but some in horizontal directions.

Motility, sensibility, coördination, reflexes, and electrical reactions normal. The only neural symptoms noticed, were localized fibrillary twitchings of the right teres major and infraspinatus muscles.

Case IV.—(Multiple skin fibromata. Few nerve fibromata. Symptoms doubtful.)

C. G., sixty years old, is being treated at the Montefiore Home for chronic bronchitis and emphysema. Patient complains, in addition to symptoms depending upon her pulmonary condition, about attacks of neuralgia and spasms of left upper extremity.

Family history in reference to neurofibromatosis is negative. Scattered over upper extremities and on abdomen are tumefactions of different size, none on lower extremities, face or head. The largest tumefaction is about the size of a cherry; its consistency is semi-elastic. There is one small vascular nævus in skin of abdomen. The large nerve-trunks are apparently free from swellings, excepting the left brachial plexus, in which a few nodules, the size of a small bean, are palpable. These nodules are somewhat tender to pressure.

There is a distinct atacti-form tremor of left upper extremity, a generalized hyperalgesia, no other neural symptoms.

In conclusion, we believe the following points deserve emphasis: (1) The possible diagnostic aid to be derived from the presence of skin fibromata or nævi in obscure lesions of the nervous system. (2) The chorei-form muscular twitchings observed in the first case. A similar condition was noted by Virchow, and in a case recently reported by Dr. Thomas to the Johns Hopkins Medical Society (*Medical News*, January 24, 1903, p. 183). (3) The absence of characteristic root pain in a case of extra medullary compression of the cord. (4) The fact that neurofibromatosis is occasionally the cause of increased intravertebral or intracranial pressure. (5) The presence of neurofibromata without giving rise to neural symptoms. (6) The indications for surgical interference are given not only by direct neural symptoms, but by the consideration of the fact that sometimes, although rarely, neurofibroma may assume a malignant character and undergo sarcomatous transformation. (7) That the absence of neural symptoms may be explained partly by the presence of an interfibrillary œdema and succulent myxomatous tissue within the hyperplastic fibrous tissue, thus diminishing and distributing the pressure; and partly by the absence of a tendency for this fibromatous tissue to contract, in contradistinction to inflammatory hyperplasia.

The Occurrence of Rhodan in the Nasal Secretion and Its Absence in Ozæna.—Muck has demonstrated the presence of rhodan in the normal constituents of the nasal secretion and states that it is principally derived from the serous glands. The amount differs in different individuals. In twenty cases of ozæna examined, no rhodan was found in any except that in one case a very weak reaction occurred with the usual tests of ferric chloride and iodine. These results correspond to the histological condition of the atrophic nasal mucosa in which the glandular cells have atrophied. Fatty degeneration of all glandular epithelium is the most constant condition present in ozæna; consequently the serous secretion is diminished in quantity and its constituent parts must decrease. He cannot say whether the fetor in ozæna can be traced at all to the absence of rhodan.—*Archives of Otology.*

Sterilizing Catgut Ligatures.—Take the ordinary commercial, formalin catgut, of known tensile strength, wind loosely in small skeins or spools, place in a small metal cylinder having an impervious screw top, fill up cylinder with xylol, screw on cap securely and place whole in sterilizer and boil for half an hour. Store in 5 per cent. carbolic acid in methylated spirits. Catgut so prepared keeps indefinitely, is not weakened, and is fully reliable.—Mayo Robson.

ORGANIZATION OF THE BUREAU OF PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.*

By WALTER WYMAN, M.D.,
SURGEON-GENERAL, U. S. PUBLIC HEALTH AND MARINE HOSPITAL SERVICE

GENTLEMEN, I beg leave to express my pleasure in meeting you at this assemblage, called by myself in accordance with Section 7, of the act of Congress approved July 1, 1902.

What may be the result of these annual conferences time must determine, but certainly we may consider the present, the first annual conference under the law, as a most noteworthy event. For the first time in the history of the United States there has been placed within its statutes, by the act of Congress referred to, a provision looking to harmonious and cooperative efforts in public health matters between the National Government and the State governments.

This status has long been desired, but difficult of achievement by reason of our Republican form of government. It has been difficult for the national government to extend its influence into State health matters without appearing to infringe upon the States' authority, and it has been difficult for the States, individually or collectively, to seek aid from the government without appearing to surrender authority reserved to them by the national constitution. In the meantime, however, the Marine Hospital Service, now bearing the title of the Public Health and Marine Hospital Service of the United States, has become so developed and strengthened, and the State health organizations have been so perfected, that a sentiment of respect, one for the other, has been established, finding its expression in this law of 1902, and, in particular, section 7 above referred to.

To my mind the outlook is bright. The great problems to be solved in sanitary affairs; the great work to be done in the suppression, and even elimination, of disease, and the cultivation of health and strength, so that physically, as well as in other respects, the United States may take a leading position among the nations, are propositions which should not be considered impossible of solution, and a proper development under the terms of this law will be an important step in this solution.

One of the most important features of this assemblage is its official character. All of us are familiar with conventions of similar purpose, productive of much useful information, but entirely lacking in official significance. Here, however, are assembled the legalized health authorities of the States, representing the practical administrative experience as well as the theoretical and scientific knowledge required in the consideration of public-health affairs.

Many of you have devoted the best years of a long professional life to the consideration of the subjects which will come before us, having acquired, in individual instances and on special subjects, unusual knowledge and wisdom.

Combined effort appears to be a distinguishing feature of this new twentieth century. This is seen in nearly all forms of civic and commercial life, and even scientific and professional effort. It would seem that when the history of the twentieth century is written there will be lacking those great and single characters looming way above the average, leading, directing, or dictating; instead, there will be an elevation of the average the best individual effort will, neither in purpose nor effect, aggrandize the individual, but will be exerted in connection with other effort of like nature for the establishment of a parity of well-being among all. This, I take it, will be the keynote of our action, bearing constantly in mind the actual results to be attained and being determined to attain them.

Section 7 of the law under which this conference has been called, provides for three kinds of conferences: First, the Surgeon-General may invite as many of the health and quarantine authorities as he deems necessary, not more than one from each State, Territory, or District of Columbia, to a conference, whenever, in his opinion, the interests of the public health would be promoted thereby. Second, a conference must be called at least once a year of all the States, Territories, and District of Columbia. Third, upon the application of not less than five State or territorial boards of health, quarantine authorities or State health officers, he must call a conference, but in this event only those States joining in the request are to be called.

While the present is the first annual conference, it is not the first conference called under the law. Last January, upon the request of twenty-two States, a so-called plague conference was called to consider the situation in San Francisco. The proceedings of that conference in detail have been transmitted to each of you. The effect of it was, undoubtedly, very great in bringing about the present satisfactory status in San Francisco. The object of that conference was specific, but, as you will note, the law providing for the annual conference gives no details. We must assume, therefore, that the intent of the law is that we shall get together, and we are to decide ourselves as to the matters to be considered. It is evident that the conference is advisory in character, without changing in the least the present executive force of this Bureau of the Treasury Department.

It seems advisable at the outset, and for a satisfactory understanding of one another, to give a review of the laws and of the organization relating to the Public Health and Marine-Hospital Service, and to receive in return an account of the same nature from each State delegate.

The laws especially relating to the United States Public Health and Marine-Hospital Service can be found printed with the U. S. Quarantine Regulations, with the exception of the Sundry Civil Act approved March 2, 1901, which provided for a laboratory "for the investigation of infectious and contagious diseases, and other matters relating to the public health."

Having thus referred to the law, I propose now to describe the organization of the Bureau of the Public Health and Marine-Hospital Service. For executive administration, the Bureau is divided into six divisions, each presided over by an assistant surgeon-general. There is also a miscellaneous division, presided over by an assistant surgeon, and the office of the chief clerk. The clerical force numbers about twenty. These divisions are named as follows:

Division of Marine Hospitals and Relief.
Division of Domestic Quarantine.
Division of Foreign and Insular Quarantine and Immigration.
Division of Sanitary Reports and Statistics.
Division of Personnel and Accounts.
Division of Scientific Research.
Miscellaneous Division.

Division of Marine Hospitals and Relief.—To this division are sent all matters relating to the marine hospitals, twenty-two in number, owned by the

*Opening address delivered at the first annual conference of State and National Health Authorities under the act of July 1, 1902, Washington, D. C., June 3, 1903.

service, and to the patients, numbering 58,000, treated annually in these hospitals and in some 110 relief or contract stations. The Purveying Depot, a large building located in New York, is under the direction of this division, to which is also referred all matters relating to hospital supplies, including subsistence, drugs, hospital furniture, surgical instruments, and appliances, plans and specifications for hospital construction, and the conduct of the sanatorium for consumptive patients at Fort Stanton, New Mexico, where the service has a sanitary ranch, fifty-six square miles in area, the buildings of the fort having been placed in perfect condition, the patients in the sanatorium numbering about one hundred and fifty. The scheme for this ranch embraces the removal of consumptives from our hospitals with a view to their improvement or recovery. Quite a large percentage have recovered, a number leave greatly improved, and all who desire can find employment after leaving in the same high, dry, and healthy locality. The hospitals are thus relieved from this contagious disease, and the vessels from which they come are subject to inspection and disinfection as to their forecastles or other quarters that have been occupied by known consumptive cases.

Division of Domestic Quarantine.—To this division are referred all matters relating to the national maritime quarantine stations, embracing nineteen complete disinfecting stations, and eighteen inspection stations. At the former are hospitals, barracks, disinfecting machinery, steamers, and small boats, all requiring constant care and attention. This division also must see to the expenditure of appropriations for new stations, involving purchase of lands, construction of piers and buildings, said construction being generally under the supervising architect of the Treasury on plans approved by the Bureau and the Department, but occasionally the Bureau attends to this construction itself. To this division are also referred all matters relating to the quarantine regulations and their interpretation. Matters relating to interstate quarantine and suppression of epidemic diseases are also handled in this division. Quarantine upon the Mexican and Canadian borders is also conducted through this division.

Division of Foreign and Insular Quarantine and Immigration.—To this division is assigned the management of the national quarantine stations in Hawaii, Porto Rico, and the Philippine Islands, the supervision of officers detailed for duty in the office of the United States consuls in foreign ports, who sign the bills of health with the consuls. At present there are three officers in Japan, Yokohoma, Kobe, and Nagaski; two in China, Shanghai, and Hongkong; one in Naples, Italy; ten in Cuba, three in Havana, one each at Cienfuegos, Santiago, Nuevitas, and Matanzas, and several at sub-ports; four in Mexico, two at Vera Cruz, one at Progresso, and one at Tampico; six in the fruit ports of Central America, namely, Bocas del Toro, Columbia, Port Limon, Costa Rica, Bluefields, Nicaragua, Ceiba, and Puerta Cortez, Honduras, Livingston, Guatemala, and Belize, British Honduras.

To this division are also referred all matters relating to the medical inspection of immigrants, a most important function of the service, requiring the detail of a large number of officers.

Division of Sanitary Reports and Statistics.—This division is charged with the preparation of the Public Health Reports, published weekly by the bureau. All matters of a statistical nature are referred to it.

It may be of interest to state that some question has arisen as to whether the work of this division, which is authorized both by the law of 1893 and the law of 1902, may not duplicate the work of the Census Bureau, but I am pleased to state that after conference with the chief statistician of the Census Bureau and others connected therewith, it has been found that there need be no duplication or interference by one bureau with the other; on the contrary each will be helpful to the other. The Census Bureau, in addition to the decennial census, will publish an annual census of mortality and births, but the weekly and monthly reports will be published as heretofore by this bureau, and morbidity reports, which are so much desired, and which will require special organization to procure, will be undertaken by the Public Health and Marine-Hospital Service.

Division of Personnel and Accounts.—To this division are referred all matters relating to the personnel of the service, examinations for admission to the corps of commissioned officers, examinations for promotion, appointments and resignations, appointment of boards for the physical examination of officers of the Revenue-cutter Service. This division has, also, charge of the bookkeeping of the service.

Division of Scientific Research.—This division might be better called the Division of Scientific Research and Sanitation. To it is referred all matters relating to the Hygienic Laboratory. It should be understood that this laboratory, or the staff thereof, is not a part of the bureau proper, though at present located in the same building. A new building, however, is just completed, located on the grounds of the old Naval Observatory, about half a mile west of the White House on the river bank. Five acres of this tract were turned over from the Navy Department for the establishment of this laboratory. It will give the director of the laboratory great pleasure to arrange with the delegates to this conference to show them this building. The laboratory has an advisory board, consisting of a delegate from the army, not yet named, Dr. Urie of the navy, Dr. Salmon, chief of the Bureau of Animal Industry; Professors Welch of Johns Hopkins; Flexner of Rockefeller Institute; Sedgwick of the Massachusetts Institute of Technology; Vaughan of the University of Michigan; and Wesbrook of the University of Minnesota. Under the law of 1902 three new divisions were added to the laboratory, the Division of Bacteriology already existing. These three new divisions are those of Zoology, Chemistry, and Pharmacology. But one of these new divisions has been organized, namely, that of Zoology, and the good results of this new organization are manifested in the recent discoveries and published report of the chief of this division, Dr. Stiles, upon the prevalence and geographical distribution of the hookworm. Bulletins, embodying important results of investigations, are published from time to time under the supervision of the director of the laboratory, Dr. Rosenau. It is believed that Congress can be influenced to provide for the extension of this laboratory by the erection of new buildings from time to time as the necessity therefor becomes demonstrated.

To this division of scientific research and sanitation are referred special requests for scientific investigation of special diseases, as, for example, the recent investigation of the so-called spotted fever of Bitter Root Valley, Montana. The initiatory steps for special investigations of this character are taken in this division, but any prolonged or technical work connected therewith is turned over to the laboratory.

Requests for special investigations of water pollution or local causes for the spread of typhoid fever are referred to this division.

The officer in charge of this division examines all current literature relating to scientific medicine or sanitation and keeps a card index of the same.

Miscellaneous Division.—The Miscellaneous Division has charge of the mailing of all bureau publications, and certain miscellaneous duties relating to the reports of necropsies from the marine hospitals, the medical examination of claims for benefits on account of injuries received by the crews of life-saving stations, certain matters relating to the the annual report, etc.

Under certain bureau orders the operations of these several divisions are coördinated, so that the work of one division, where it affects the personnel of duties connected with another division, is accomplished with the full knowledge and acquiescence of the other. There are also two regular bureau boards for the careful consideration of matters referred to them—namely, the Service Board and the Sanitary Board.

Yellow Fever Institute.—There is one other feature of the bureau, assigned to no one particular division, but embracing all, namely, the institute for the study of yellow fever, called the Yellow Fever Institute, with which most of you are familiar. This institute was founded about two years ago for the purpose of learning all that could be learned about yellow fever, including its etiology, and to bring to this work the aid of all reputable physicians who might desire to take part therein, its membership including, besides the officers of the Marine-Hospital Service, special investigators both in this and foreign countries. It is divided into four sections, the chairman of each section being one of the division officers of the bureau to which, under bureau organization, matters of a kindred nature would naturally come. These, together with the chairman and secretary of the institute, form an executive board to consider, especially with regard to publications, the contributions received from the members. Twelve bulletins have been issued. A thirteenth, and the most important of all, relating to the cause of the disease, is now being printed and will be ready for distribution within a few weeks. This bulletin contains the report of a working party sent to Vera Cruz last summer to investigate and attempt to find the causative agent of the disease. Their work was continued during the winter with the material obtained in Vera Cruz, and gives evidence that progress has been made toward a final result. A second working party of three, two of whom were in the first party, are now in Vera Cruz and vicinity pursuing a continued investigation, and it is the purpose of the institute to continue in the prosecution of this work until successful. This institute embraces new features in the investigation of the cause of a specific disease, and if it proves successful with regard to yellow fever it may be that the new features of organized effort which it embraces will be applied to the investigation of other diseases.

Other important matters engaging the attention of the service are the proposed legislation for the establishment of a national leprosarium, in which may be received the occasional cases of leprosy found in the States and which give the local and State authorities so much trouble; also the enforcement of the new regulations relating to the examination and licensing of establishments for the production of vaccine, serums, and antitoxins, under the law passed by the last Congress. These regulations go into effect next August.

Mention should also be made of the connection of the service with the International Sanitary Bureau of American Republics, established in accordance with resolutions of the conference of American States held in the city of Mexico winter before last.

The Medical Corps.—Finally, with reference to the service work, I wish to say a few words with regard to the medical corps, numbering 108 commissioned medical officers, received into the corps only after a thorough examination as prescribed by law, appointed first to the lowest grade, and promoted to the higher grades only after further successful examination. The discipline of the corps is military in character, the regulations for its uniforms and government are prescribed by the President, its officers by reason of unusual responsibilities, continuous medical and surgical care of the large clienteles, and by special scientific instruction in its hygienic laboratory, are kept in the van of professional excellence. There are, however, nearly two hundred acting assistant surgeons, some of whose appointments are temporary in character, but a number of whom have been long in service by reason of especial adaptability, or because the arrangement made with them is necessary in the interest of economy. These officers of the medical corps are stationed in all parts of the United States and its dependencies, and constitute our reliance not only in the ordinary work of the service but in times of special need.

Conference Organization.—I have deemed it necessary to give this somewhat extended account of the organization of the service, both that our aims and methods may be understood and that I may the more readily explain a proposed method of making these annual conferences of practical utility. It might be advisable to appoint on special committees members of the conference especially interested in the several subjects to be considered by these committees, said committees to remain in organization during the year, and to receive for further conference with the Surgeon-General such matters as might be pertinently referred to them by him. The titles of these committees would find their analogues in the several divisions of the bureau. The reports of these committees could be read to the full conference at its annual meeting, and, if adopted by the bureau and the conference, would have a force and influence which would naturally result from the conjoint action of the national and State authorities. I would suggest tentatively a committee on scientific research and sanitation; second, on the prevention and spread of epidemic diseases; third, on morbidity and mortality statistics; fourth, on State legislation; fifth, on education. In addition to these, there might be special committees on certain specified diseases, namely, cholera, yellow fever, plague, smallpox, tuberculosis, leprosy, typhoid fever. To these committees might be committed such resolutions as may be offered here, but the adoption of any resolutions by this conference, it seems to me, should not be until after a report thereon had been made by the special committee to which it is referred.

It is believed that the above plan is at least worthy of trial. It would give real aid and would stimulate the members of the committees in an investigation of the subjects confided to them, and might produce a uniformity of effort, a coördination of work in different parts of the country, which now does not obtain.

DIAGNOSTIC AND PROGNOSTIC DATA IN NERVOUS AND MENTAL DISEASES.*

By WILLIAM BROADDUS PRITCHARD, M.D.,

ADJUNCT PROFESSOR OF MENTAL AND NERVOUS DISEASES, NEW YORK POLYCLINIC; CONSULTING NEUROLOGIST, SMITH INFIRMARY, STATEN ISLAND.

Diagnosis in neurology and in mental disease demands consideration from two standpoints: the general and the specific. It is difficult to decide as to relative precedence, since both are equally important, and indeed essential, to a finished and satisfactory result. Breadth in perspective is of the utmost value in the working equipment of the neurologist and alienist. The collateral territory is larger than in any other sub-field of medicine. The issues in surgery are, as a rule, direct and relatively narrow. The same is true of ophthalmology, dermatology, and other branches. The most intimate and essential relationship exists between nervous diseases and all other diseases. An old history of renal colic in a neurasthenic may prove, for example, the guiding factor in treatment. The melancholiac would be oftener a therapeutic mystery should due appreciation be not given to the *μελας χολή* present. Autointoxication from stomachic or intestinal deficiency is often the causative factor behind a neurosis or a psychosis. The dependence of all bodily functions upon the integrity of the related nervous supply and action is conspicuously obvious. Hence the neurologist must be an evolutional development from the general practitioner. The ophthalmologist *may* be born; the neurologist *must* be made.

By collateral territory requiring consideration, I mean such factors as race, environment, temperament, occupation, age, sex, social and educational status, heredity, etc. Take the racial factor, for example: The Latins represented in the French and Italians are a nation of neurotics; the Jews are inherently and peculiarly predisposed to the degenerative nervous affections; Asiatics are relatively exempt from the neuroses major and minor; certain nervous diseases occurring in the negro assume a clinical form, which is almost *sui generis*, as tabes, for example, which in the negro is almost invariably of the amaurotic or blind form. Temperament is related to race. The emotional tends to the neuroses; the phlegmatic to the psychoses. Hysteria is common among the French, melancholia among the Germans; mania, and particularly so-called religious mania, in the Irish. Detailed study of the temperament is of special importance, and should always be made exhaustive, since the personal equation depends upon it and an exact knowledge of the personal equation is often the determining factor—the key-note—in results. Neglect of this equation prevents a sympathetic understanding, lessens your patient's capital in confidence, and by so much diminishes your chances of successful results from treatment.

Environment is sometimes a significant factor. Neurasthenia is much more common among residents of the city than the country. This is true also of chorea, and since syphilis is a disease of the city, its sequential nervous manifestations are much more frequent in metropolitan practice. Age, sex, and occupation are of especial etiological interest. Chorea, poliomyelitis, and (to a less degree, perhaps), epilepsy are all diseases of childhood. Posterior sclerosis and its cerebral equivalent, paretic dementia, are diseases of adult life. Women tend to the minor, men to the major neuroses. Organic disease of the nervous centers is more common in males than in females. Neurasthenia and kindred affections are so peculiar to the cultured, educated classes as to appear almost a penalty. It is a waste of time to hunt for neurasthenia, except the traumatic form, in the uneducated laborer; the diagnosis would make a paradox.

Heredity is of more importance relatively in the prognosis than in the diagnosis of nervous disease and insanity.

Coming to the more direct aspect of the subject, I would urge with vigorous emphasis and as being of the utmost importance, the cultivation and education of the physician's objective or perceptive faculties—vision, hearing, and touch, and the training of these faculties into syndrome association habits. The facies alone of the neurological patient at times decides the diagnosis. Asymmetry and anomalies of development in features and peculiarities of expression all tell some story or point a road. The facies in melancholia, in Graves's disease, in Bell's palsy, and often in dementia, is pathognomonic. The position in standing or walking, or in rising from a sitting position, may name the disease. The rigid attitude, blank face, head bent forward, so characteristic of well-marked paralysis agitans, are readily recognized when one is familiar with the disease. The gait in tabes, legs wide apart, eyes on the floor, feet brought down on the heel with unnecessary force, is unmistakable. The teetering shuffle in spastic paraplegia, the stiff half-swing of hemiplegia, the flaccid drag of poliomyelitis or multiple neuritis, are all distinctive. I know nothing more characteristic than the method of climbing up his own body practised by the victim of pseudohypertrophic paralysis in rising from a prone to the upright position, so graphically described by Gowers. It has been said of the elder Charcot that he often made the correct diagnosis before seeing the patient, the ear identifying the disease from the special gait of the patient as he approached. The trained ear learns readily to catch and identify the speech peculiar to bulbar palsy, to paretic dementia, and to disseminated sclerosis.

The sense of touch is one of the most valuable, and, at the same time, neglected aids in refined diagnosis. The presence or absence of atrophy, for example, often decides the diagnosis and also the prognosis and line of treatment. The eye cannot always be relied upon. In infantile spinal paralysis the loss of power is often widespread at first. It is important to know where and to what degree the permanent residual paralysis exists. This is indicated by the atrophy. The contour of the limb in which atrophy exists may not be altered, and this is especially true in fat, chubby children. The sense of touch, if educated by training, will settle the problem much more certainly than the eye. Hemiatrophy of the tongue is often apparent to the sense of touch when vision discloses nothing. The difference between contraction and contracture, often quite important, is determined by the tactile and muscular sense. The twitch of chorea when latent, in cases just developing or on the road to recovery, is at times determinable only through tactile impression. Paralysis, even when slight, is readily detected by forced movements in opposition to the patient's resistance. The sense of touch plus the examiner's muscular sense far exceeds in nicety and accuracy of impression the dynamometer in estimating motor power. The hand is more accurate in testing the deep reflexes than the percussion hammer.

The advantage from training the perceptive faculties into association habits is found in the result-

*Read before the Clinical Society of the New York Polyclinic.

ing prompt recognition of the diagnostic significance of certain symptoms when met with in combination. Headache, for instance, is a very common symptom. There are several distinct varieties, and some of them in their peculiarities are highly suggestive at least. The headache of intracranial syphilis is peculiar in its nocturnal or vesperian periodicity; that of melancholia in its localization in the occipital or post-cervical region; the headache of brain tumor in its agonizing severity. Insomnia also varies with equal significance. The insomnia of brain syphilis is usually of the first half of the night; and of the latter half in melancholia. The characteristic insomnia of neurasthenia is light, restless, half-sleep throughout the night. Combine several such facts in mental association, and the result is a series of diagnostic formulæ or syndromes. That for the recognition of cerebral syphilis is one of the best known and quite reliable. It is as follows: Given a patient suffering from cerebral lesion, whose age is between twenty-five and forty-five years, whose lesion was preceded by nocturnal or nocturnally exacerbated headaches, the headaches being associated with insomnia of the first half of the night, both insomnia and headache disappearing for the time, at least, upon the onset of the lesion, such lesion is due to syphilis. The variety of headache and insomnia described as peculiar to melancholia, if found associated with the facies referred to and a tendency to suicide, constitute the melancholic syndrome and afford sufficient data for diagnosis.

The prognosis in nervous diseases and the insanities is far better than is generally supposed. I believe the proportion of recoveries is as great as in almost any other specialty. Certain forms of nervous disease are, however, hopeless. I have yet to know personally of recovery in general paresis, Landry's palsy, or multiple sclerosis. Decided benefit may be obtained from treatment in tabes, in paralysis agitans, and in epilepsy. The prognosis in neuritis and in the neuralgias is nearly always favorable, although tic douloureux is often viciously intractable and sciatica obstinate. Excluding the tuberculous variety, more than 50 per cent. of recoveries occur in meningitis. The most discouraging cases of myelitis, especially when traumatic, may turn out well, and many hemiplegias, especially if syphilitic, recover. A syphilitic etiology favorably modifies the prognosis in mental and nervous diseases except in tabes, general paresis, and epilepsy. Among the insanities, all of the non-organic types are recoverable, and the majority give excellent and prompt results from treatment. A vicious heredity always makes worse the prognosis. The more anomalous the type is in epilepsy, chorea, and the neuroses generally, the better, as a rule, the prognosis. Etiology is relatively unimportant in its bearing upon prognosis in many of the neuroses. Removal of the cause to be effective in promoting cure must be prompt—so prompt, indeed, as to almost precede a diagnosis. If allowed to continue, a vicious habit is induced, which persists in spite of the removal of the cause. This is an important fact to be borne in mind in estimating the prognosis in traumatic epilepsy, in reflex chorea and other neuroses, in various neuralgiæ, and in certain monopareses.

105 West Seventy-third Street.

Vaginismus.—In obstinate vaginismus Tavel resects the pudic nerve. An antero-posterior incision is made in the ischio-rectal fossa, midway between the tuber-ischii and the margin of the anus. The nerve is freed from the accompanying artery and divided. The peripheral portion is twisted out.—*American Journal of Obstetrics*, October, 1902.

AUTO-EPIDERMIC SKIN-GRAFTING.

By H. F. McCHESNEY, M.D.,
BROOKLYN, N. Y.

Skin-grafting is a subject that has been worked out in a very thorough manner, because of its importance in cutting short the healing time, in cases of extensive destruction of skin, and in cases in which there would be contractions leading to deformity if left to fill in from the uninjured area surrounding. It is the aim of this paper to call the attention of the profession to a method of auto-epidermic skin-grafting, which, in the author's hands, has proved painless and practicable.

The first case on which the method was used is as follows: The patient, D. K., a Greek, age eighteen years, admitted to the Brooklyn Hospital, on the service of George R. Fowler, M.D., December 9, 1902, was burned by the explosion of a gasoline peanut-roaster, receiving a slight burn on the left hand and burns of the third degree on both legs and thighs.

The right extended from five inches above the knee to a line represented by the shoe top, and in the leg region extended all the way around. The the left leg was burned deeper and extended from seven inches above the knee to the line of the shoe top, and in this case extended all the way around the leg and knee.

The first dressing consisted of sterile gauze and "carron oil." This was removed the following day and all loose epidermis and blebs removed, and the parts irrigated with warm carbolic solution, then wet dressings of normal salt-solution were used for a time. When the skin began to slough the patient was put under an anæsthetic and everything cleaned away, leaving a granulating surface. The dressing was then changed to a 2 per cent. boric-acid wet dressing and naphthalin crystals were powdered on to clean up the granulating surface. Boric-acid ointment was then applied on strips of gauze, but the temperature began to rise, and as no cause other than lack of drainage could be found. The dressing was again changed to a wet boric acid. When the granulating surface cleaned up, the dressing was changed to the following formula:

℞ Icthyol	℥	300
Balsam peru	℥	150
Resorcin	gr.	150
Comp. alum (Squibbs)	gr.	300
Boric acid	℥	i
Glycerin	℥	viii
White wax	℥	viii
Petrolatum	q. s. ad. lbs.	iv

There was no subsequent rise of temperature.

At this time skin-grafting was started, and the method here advocated was employed. The area to be grafted was cleaned off with Tiersch solution and then irrigated with normal salt-solution. The granulating surface was then dried with gauze sponges. Where the granulations were firm and healthy, the graft was placed directly on them; over areas of exuberant growth they were cut down and gently compressed with dry sponges until all bleeding stopped. Some of the granulations were very soft and flabby. These were all scraped away until a firm fibrous foundation was reached. Then the thin blue line of epithelial cells that had started to creep in along the edge of the wound was dissected up, and small pieces about an eighth of an inch square were cut off and placed on the granulating surface already prepared. These were placed with the raw surface against the newly prepared surface, and covered with pieces of oiled silk protective about an inch square, other transplanted areas were protected with plain sterile gauze. The limb was then

put up in a Volkman sprint to prevent contractures and also to keep the parts quiet, so that the grafts would not be displaced.

The patient experiences but little discomfort while the epithelial line is being raised and cut off. It does not disfigure or scar, and at each dressing several new islands can be started without discomfort to the patient. These newly developing epithelial cells are very active in their growth and the grafts take very well. As far as we can learn, this method of skin-grafting has not been published and, as the number of cases available for a thorough testing of the utility of this method of grafting is limited, we would be pleased to have cases reported.

Brooklyn Hospital.

REPORT OF AN OPERATION FOR CARCINOMA OF THE CÆCUM AND ONE OF CARCINOMA OF THE TRANSVERSE COLON.

By C. G. DARLING, M.D.,
ANN ARBOR, MICH.,
AND
DEAN LOREE, M.D.,
ANN ARBOR, MICH.

Mr. J. Z., age forty-six years. Occupation, a grocery clerk, formerly a day laborer. He was of Polish parentage, married, and the father of twelve children, all living, and in good health. He was admitted to the Medical Department of the University Hospital July 29, 1902, and referred to the Surgical Department July 30, 1902. He came to the hospital because of swelling and pain in the right side, first noticed about eight weeks before admittance. He had also been annoyed by borborygmi in the tumor region, generally followed within a short time by the passage of a soft stool. He was cachectic, had lost twenty-five to thirty pounds, but yet in good condition to withstand the shock of an operation.

Percussion of the abdomen revealed a mass about as large as a medium-sized orange with an irregular surface, situated in the right iliac region and extending up to about one inch above the level of the umbilicus. The tumor was hard to the touch, freely movable and readily observable on inspection. The diagnosis of carcinoma of the cæcum was made and an operation advised.

Operation.—Patient came to operation August 2, 1902, at 9.42 A.M., and was sent to his room at 12.32 P.M.—actual time of operation being two hours and fifty minutes. A period of eight minutes was required to anæsthetize with four ounces of ether used. The total amount of ether for the entire operation was twenty-two ounces. During anæsthesia and recovery from the same he received $\frac{1}{30}$ grain of strychnine hypodermically. Twenty-two ounces of decinormal saline solution was given under the right breast and one-half pint of coffee per rectum. Respirations were from 24 to 30. The pulse was not above 90 at any time.

The technique of the operation began with an incision along the outer margin of the right rectus muscle, beginning about two inches above the umbilicus and extending downward four inches. Through this initial incision the tumor mass could be directly palpated, the extent and location of the adhesions determined, and the chances of its successful delivery estimated. It was not attached to the anterior abdominal wall and seemed freely movable upon the structures below at its upper extremity, but at its lower pole was quite firmly adherent to the iliac vessels. A second incision was next made at right angles to the first and extending about four inches to the right. The separation of the mass began from the outer side and was carried beneath the mesocolon, care being taken to avoid injury to the ureter. Great difficulty was experienced in separating the infiltrated peritoneum from the iliac vessels, this, however, was slowly and successfully done and at no time was there any severe hemorrhage. The appendix was small and, so far as the naked eye could detect, was not involved in the malignant process. After separation of the adhesions, an intestinal clamp was placed upon the ileum about four inches from its junction with the cæcum and a tape was passed around the colon well above the point of disease. About three inches of the ileum and six inches of the colon were removed. The ends of the colon and ileum were then brought together and joined by a silk suture, passed from within out and embracing all the coats of the small gut except the peritoneum, this stitch occupying the space between the folds of the peritoneum which form the mesentery.

It was then returned from without inward through the colon in like manner as before and tied on the lumen side. A single suture was then inserted on either side of the first and carried through all coats of both ileum and colon, thus approximating the peritoneum of both cut ends and reinforcing the weak point in end-to-end anastomosis. Beginning with the above points of union a continuous suture was passed through all the coats for a distance, and a second one started at a like point on the opposite side, the object of the use of two sutures alternating in this way was to gather the wall of the larger gut uniformly, so that its diameter would equal that of the smaller one, a proceeding that applied well in this case when the two ends of bowel were about the same size. The union was completed by a row of Lembert sutures about two lines from the first. All remaining bleeding points were caught and ligated. The omentum was then drawn over to the outside of the line of intestinal repair and sutured to the parietal peritoneum, thus covering as much of the suture line as possible with peritoneum. Two large gauze drains were passed down to the omentum immediately covering the suture line and emerged at the lower angle of the first incision. In closure of the external wound, cat-gut stitches were used for the peritoneum, layers of fascia and the cut ends of muscle, the latter being reinforced by silkworm gut which approximated the skin.

After recovery from the anæsthetic he complained of some nausea, but did not vomit, neither did he do so at any time during his sickness. He had some pain in the region of the wound, for which he was given $\frac{1}{4}$-grain of morphine at 8.30 P.M. The pulse did not go above 70, temperature 99.6°, and at 12 M. he voided 300 c.c. of urine. At 10.30 P.M. he received six ounces of decinormal saline solution per rectum, which he retained. After 9 P.M. he slept twenty, thirty, and forty-five minutes at different times.

Second day.—The highest temperature was at 1 A.M., 100.8°, and highest pulse rate for the day was 92. He received $\frac{1}{30}$ grain of strychnine every seven hours. At 4 A.M. and 10 A.M. he was given six ounces of decinormal saline solution per rectum. At 7 A.M. drachm measures of hot water were begun and kept up every half hour until 11.30 A.M. This having caused no vomiting he was given six drachms of cold water, after which he received drachm measures of the same every hour. Between the hours of 3.30 P.M. and 7 P.M. he retained 13 drachms of weak broth by the stomach.

Third day.—Highest temperature 100°, pulse 100, respiration 32. He complained of some pain in the wound, but a more alarming symptom was cough

and pain in the upper thorax, perhaps presaging an anæsthesia-pneumonia. For pain and cough $\frac{1}{8}$ grain of morphine hypodermically and ten-drop doses of aromatic spirit of ammonia by the mouth were given. An ice-bag was applied to the chest, which was continued for some days and afforded great relief. This treatment rendered the cough less and the secretion more profuse. The cough continued for several days, but seemed to be due only to a catarrhal condition of the bronchi. It hindered the healing of the wound to some extent, as it kept up a frequent action of the wounded muscles. He received his strychnine as on previous days. His nourishment consisted of 13 drachms of weak broth, and in all 33 drachms of water per stomach. At 7.30 P.M. he was given a nutritive enema, consisting of six ounces of milk and the white of one egg. This was not carried high into the rectum. At 8 A.M. he passed a normal, partly formed stool. He slept at intervals, in all nine hours.

Fourth day.—Highest temperature 101.4°, pulse 99, and respiration 32. He still had a good deal of pain in his throat and chest and continued to cough. He had strychnine and aromatic spirit of ammonia as previously.

His diet consisted of five ounces of weak broth, and two to four-drachm measures of water at intervals during the day. He also had nutritive enemata of peptonized milk and white of egg at intervals of five hours, the first and second of which were partially expelled, the latter containing a small quantity of fecal matter. The one given at 1 P.M. was retained, while that given at 7 P.M. was expelled. During the day he slept in all about six hours.

Fifth day.—Highest temperature 99.4°, pulse 88, respiration 26. Diet consisted of four ounces of broth per stomach, with water at intervals. He also had four nutritive enemata, all retained but one. He passed one watery stool. Remedies were administered as before. At 10 A.M. his wound was dressed for the first time, the gauze drainage being removed. There was an abundant discharge of chocolate-colored fluid, in which bacteriological examination showed the presence of colon bacilli. It had a decided fecal odor, but seemed to originate from outside of the peritoneum and was no doubt only an external wound infection due to contact with the open gut. After a few days this discharge changed to one of a creamy color, which continued until the wound closed. At the first dressing, a sterile rubber tube was inserted in place of the gauze and another at the upper angle of the first incision. From this time to recovery the wound was dressed twice daily, the tubes being removed and shortened as indicated. The abdomen about the wound was kept clean, but no irrigation internally was at any time employed.

Sixth day.—Temperature 99.2°, pulse 73, respiration 23. The pain in the back and chest had nearly disappeared. Diet, six ounces of broth and four drachms of water every four hours. He also received four nutritive enemata. The bowels moved four times, showing some formed fecal matter.

Seventh day.—Pulse, temperature, and respiration were normal, and continued so from this time on. He had all signs and symptoms of a good recovery. Upon the eleventh day after his operation his diet consisted of baked custard, chicken broth, and cornmeal gruel. Upon the nineteenth day he was allowed coffee and bread. Twenty-nine days after operation he was discharged.

In the excellent article by Cumston and Vanderveer, published in the *Annals of Surgery*, for February, 1902, the points in diagnosis were well given and the different methods of uniting the ileum to the colon were clearly discussed, but little attention was given to those conditions and procedures upon which success depends, whichever method is employed. While we favor the suture and prefer to discard splints and buttons, yet, when time is an element, or the operator is not sure of his technique, these devices may be used. It necessarily matters little whether button, plate, or suture be used, if careful attention is not given to the principles involved in the treatment of such cases.

A study of the above cited report reveals the fact that operations for carcinoma of the cæcum have a large death rate; that death follows in some instances shortly after operation, which fatality undoubtedly results from shock or hemorrhage. Others die three to six days later, no doubt from infection during operation. Deaths later than this probably result from one of the following causes: (1) Infection involving the stitches or spreading to the general peritoneal cavity; (2) Local gangrene resulting from cutting off the blood supply or, as in certain recorded cases, pressure from the button; (3) Obstruction. In no other class of operative cases does fecal matter, even in small amount, produco such risk to the patient's life.

Its collection may cause obstruction, either partial or total, or by pressure cause the sutures to yield. This complication not only arises from unremoved fæces but may come from improper feeding, either before or after operation; or it may be brought about by the swelling of the parts. Obstruction is followed sooner or later by vomiting, producing at once a serious if not a fatal strain upon the newly-repaired gut.

Death from shock may be prevented by a careful preparation of the patient. The bowels must be emptied and stimulation by strychnine kept up. The careful administration of the anæsthetic is of the utmost importance and the proper use of decinormal saline solution may turn the tide. We are satisfied the latter procedure saved our patient's life.

The most important factor in intestinal surgery is to avoid infection of the peritoneum. Infection was present in our case, but fortunately was confined to the point of drainage. When the mass can be brought outside of the abdomen before opening, the danger of infection is slight, provided the parts can be protected with gauze and the intestines cleansed with hydrogen peroxide and plain water. The use of intestinal antiseptics for some days before operation might be beneficial, but an ideal method would be to inject some antiseptic into the confined section of bowel and remove it before excising the diseased portion. Another aid in preventing local infection is to cover the line of suture with omentum. In examining our experimental operations upon animals in the Surgical Laboratory, we have always found the omentum wrapped about the line of suture. This condition is also found in appendicitis when the omentum can reach the inflamed part. In fact, it is nature's method of protecting the line of suture and is sufficient in a large number of cases to resist an ordinary amount of bacterial invasion.

Too much stress cannot be laid upon this use of the omentum in intestinal repair, and while it is possible for adhesions to form and be followed by obstruction some months later, that is a remote danger and not to be considered with the immediate one of rupture. The stitches forming the anastomosis may not yield for many hours if properly placed. By this time the omentum has become adherent to the intestine and renders efficient service by its reinforcement. Care must be taken

however, when the omentum is used to cover a weak point that it is held in place by the fewest possible absorbable sutures, that it may be free should the adhesions disappear later. Because of the great probability of infection in these cases drainage is imperative, but as pus rarely forms until the third or fourth day, and after the sutures are well protected by omental adhesions, a gauze wick drain carried down to the omentum will direct the flow of fluids away from the locality. This drain should be removed about the fourth day, unless signs of active infection present themselves earlier, and a drainage tube be inserted in its place, care being taken not to disturb the point of repair. Should stitch abscesses form in the external wound, the sutures should be removed at once and the parts supported with gauze and collodion.

Gangrene of the intestine is frequently the result of accident, the blood vessels becoming blocked by being caught or bruised with forceps. The operator should exercise great care in not injuring or ligating vessels by which the blood supply to any part of the intestines may be cut off. Interference with the circulation is quickly manifest and death by rupture of a gangrenous intestine can be averted only by cutting out at once the part deprived of blood.

The grave consequences following obstruction call for strong prophylactic measures. The very existence of a foreign growth more or less occluding the lumen of the bowel and many times, in consequence of infiltration of the neighboring tissues, binding the cæcum down, necessarily forms a barrier to peristaltic movements. Extra precaution is necessary, therefore, to empty the whole tract of its contents, and after thorough evacuation to put the patient upon a diet that will leave the least possible residue. The above record shows that our patient received no food for two weeks that could leave any accumulation in the intestine. When vomiting occurs, the stomach should be frequently and thoroughly washed with the stomach tube.

Some points may be further emphasized by brief mention of a case of cancer of the transverse colon which was operated three days after the previous case. In this case the same method of operating was employed, about five inches of the colon being removed. At 5 P.M. of the second day he showed signs of obstruction with pain in the abdomen, great restlessness, pulse 106, temperature 101°, and later hiccough. Nothing was administered by the stomach from this time until the seventh day. An ice bag was applied to the abdomen, and the stomach was washed twice daily. Enemata of six ounces of peptonized milk with the white of one egg were given every six hours. Upon the sixth day he had a large soft movement, and on the seventh day a normal soft stool, indicating clearly that because of obstruction by the growth, fecal matter had been retained, causing a second obstruction after operation. At no other time were there unfavorable symptoms in this case, the patient making a speedy recovery, and being discharged upon the thirtieth day after operation.

An Anatomical Method of Demonstrating the Accessory Cavities of the Nose.—G. Bruehl suggests the following method: a fresh or alcohol skull is macerated one-quarter; the soft parts are dissected off and it is decalcified in a ten-per-cent. nitric acid solution. Decalcification takes longest at the glabella of the frontal bone and the zygomatic process, but is complete in two or three weeks. After washing in running water, the skull is hardened in alcohol, then dehydrated, and finally subjected to a mixture of equal parts of absolute alcohol and ether. The specimen is then placed in carbolxylol. On the following day, if the bone has been dehydrated and decalcified, it is cleared. The specimen is removed from the carbolxylol, the excess fluid is allowed to run off, and an opening is cut in the septum of the frontal sinus; its nasal canal is closed off with cotton. Wood's metal is melted in a spoon with a tapering tip. Care must be taken not to heat it too much; just enough to melt it is the best. It is then poured into the frontal sinus with the specimen held on its side. The sphenoidal and ethmoidal sinuses are then filled. The maxillary antrum is filled from an opening in the canine fossa. The amount of fluid necessary to fill the cavity enables us to determine its cubical contents. In order to improve these specimens for demonstrating purposes, after the metal has become hard, windows may be cut into the walls of the accessory cavities. Enlarged blood vessels appear through the bone. The furrows in the bone for the vessels may be outlined with water color. All the individual features of these cavities are thus capable of being demonstrated. Their position to the cranial cavity, to the mouth, to the nasal cavities, and their relation to one another, are exactly given.—*Archives of Otology.*

A New and Original Stitch and Method of Closing the Abdominal Walls and Other Deep Incisions.—Jacob Michaux takes a suture with a needle on either end, and pierces the peritoneum only on one side, bringing out the needle just under the surface of the rectus muscle (if closing an incision in the median line), passes over the rectus and catches up the aponeurosis. He then lays down needle No. 1, takes up the other and repeats the operation on the other side. The peritoneum and aponeurosis are thus pierced on both sides. The next step is to cross over, taking up the aponeurosis again (with needle No. 1), on the opposite side, carrying the needle through the fat and skin at one thrust. Then needle No. 2 is taken across the incision; the aponeurosis pierced as well as the overlying fat and skin on that side. This completes the stitch. The aponeurosis is now pierced twice on each side, thus insuring a firm hold on this important structure, and each thread, as it crosses, must draw the edges of the aponeurosis together. Upon the close union of its edges depend the exemption from hernia. The advantages of the procedure are the following: Uniform tension along the walls of incision. Close approximation of edges of aponeurosis. Complete removal of suture after healing. Simplicity.—*Virginia Medical Semi-Monthly.*

A New Form of Pathogenic Blastomycetes.—M. Santori concludes from his researches: (1) In some cases of malignant tumors, especially if they are of the nature of connective tissue, it is possible to isolate blastomycetes. (2) From a sarcoma in a rooster, the author isolated a form of blastomycetes identical with one previously isolated from a similar tumor in the same fowl, which together with Casagrandi he called Saccharomyces infiltrans. (3) This form of blastomycetes when inoculated under the skin is capable of inducing a growth of connective tissue nodules, which cannot, however, be considered true tumors. (4) In any case it provokes the formation of puriform foci, and the death of the animal sooner or later. (5) It is capable of producing pseudo-tubercles of the same structure as genuine tubercles; for which reason it might be appropriate to call it a pseudo-tuberculous blastomyces.—*La Riforma Medica.*

Puerperal Convulsions.—Apomorphin is a powerful diaphoretic almost equal to pilocarpine, without its tendency to produce pulmonary œdema. In postpartum cases of eclampsia it has been tried in doses of $\frac{1}{32}$ grain with success.—Kitchens, *St. Louis Courier of Medicine.*

MEDICAL RECORD:

WM. WOOD & CO., 51, FIFTH AVENUE.

New York, June 13, 1903.

THE PREVENTION OF TUBERCULOSIS.

ONE of the subjects discussed in the Section of State Medicine at the recent meeting of the British Medical Association was by what general scheme of action, including administrative measures, can the prevention of tuberculosis be most efficiently advanced.

Notification was, of course, regarded as one of the chief means to check the spread of the disease, although most of the speakers were not in favor of making notification compulsory.

Dr. J. Robertson of Sheffield strongly urged that sanitary authorities should have power to establish places for the open-air treatment of phthisis and other tuberculous diseases; he also drew attention to the need of the provision of isolation homes, for patients who were a source of danger to their friends and to the general public.

Dr. Ransome of Bournemouth made some remarks which were characterized by sound common sense, and which were in pleasing contrast to the views set forth by the upholders of the theory that tuberculosis is a dangerously infectious disease. Dr. Ransome pointed out the fact that tuberculous infection was much more largely conditional on individual resistance than the infection of many other diseases, and it no doubt frequently happened that an individual might harbor virulent tubercle bacilli and yet, provided he himself was strong and healthy and lived in healthy surroundings, the chances were largely in favor of his not contracting the disease. In support of his contention that the tuberculous infection was conditional upon the receptivity of the body, and to an almost equal extent on the environment of that body, Dr. Ransome mentioned some experiments in which a sample of tuberculous sputum, exposed to sunshine and air in his own house, had entirely lost its virulence in the course of a few days, whilst a similar sample of the same sputum, exposed in the room of one of the lower-class houses in Manchester, contained living virulent bacilli at the end of three weeks. The speaker urged upon the medical officers of health the fact that their great duty with respect to the prevention of tuberculosis was to improve the conditions of life—and especially the conditions of the dwellings of the poor.

Mr. J. F. Hall-Edwards believed that the establishment of sanatoriums was the best means of stamping out phthisis; at present, however, they appeared to be fostering consumption as a hot-house plant rather than treating it as a scourge. He was strongly opposed to methods which entailed the treatment of tuberculous patients for a limited time in sanatoriums, and which then simply returned them to that identical home environment which was in so large a measure responsible for the disease.

Dr. H. M. Biggs recently read a paper, in the course of which he said that the measures adopted by the New York Board of Health are partly compulsory and partly voluntary, but the former are not strictly enforced. At first the medical profession was very much opposed to the ordinances, largely because they did not properly appreciate their aim and scope. In recent years a better understanding has prevailed, and the consequence is a large and steady increase in the number of cases reported to the board. It has been found that 80 per cent. of the cases ending fatally have previously been registered. Much good has been accomplished by improving the sanitary condition of the overcrowded tenement-house districts, which were found to be the principal centers of infection. On the other hand, harm has come from calling tuberculosis a contagious disease. It is communicable but not contagious. The pressing needs now are: Hospitals for advanced cases, sanatoria outside the city for incipient cases, the inspection of workshops, and the enforcement of sanitary measures in them and in public conveyances.

THE MEDICAL RECORD has long been an advocate of controlling the spread of tuberculosis by every possible sanitary measure, including the doing away with the unhealthy ill-ventilated dwellings of the poor, unfortunately so common in all large cities, and especially in New York City. The establishment of sanitoria, too, should effect much in the fight against consumption. Nevertheless, such institutions to be successful must be conducted on thoroughly practical lines, and great care exhibited in admitting only patients in that stage of the disease likely to be benefited by such treatment. As to the question of notification, the system adopted by the New York Board of Health is best calculated to meet the exigencies of the situation. Tuberculosis, as this journal has always contended, is only communicable under certain circumstances, and therefore to render it a compulsory notifiable disease would be unjust to many of its victims, as well as, to a large extent, unnecessary.

First improve the conditions of life of the poorer classes, then treat the disease, when found, by rational means, such as sanatorium treatment, and then the prognostications of enthusiastic experts, that the time is near at hand when tuberculos will be almost unknown, may haply come to pass.

Anæsthetists for the Public Hospitals.—The Board of Managers of Bellevue and the allied hospitals has decided to appoint anæsthetists for each of the hospitals under its charge. These appointments will be honorary, and will be held by specialists, who will give instruction to the incoming members of the house staff in the art of administering anæsthetics in accordance with the best modern methods. Two such instructors will be appointed to Bellevue Hospital, and one apiece to the several dependencies, and arrangements will be made by which one hospital may call upon the services of the anæsthetist attached to another in case of the temporary absence of its instructor.

RECENT STUDIES REGARDING THE MORPHOLOGY OF THE DIPHTHERIA BACILLUS.

Dr. Arthur T. Laird read before the Medical Society of the County of Albany, on March 18, 1903, a paper with the above title. The writer has gathered together the results of the investigations of numerous American observers in regard to morphology of the diphtheria bacillus. Wesbrook, director of the Bacteriological Laboratory of the Minnesota State Board of Health, divides diphtheria into three main groups, subdivided into types. The groups are (1) granular; (2) barred; (3) solid-color forms. From a study of a series of clinical cases the conclusion is drawn that (*a*) granular types are usually the predominant forms at the outset of the disease; (*b*) the granular type usually gives place wholly, or in part, to the barred and solid types shortly before the disappearance of the diphtheria-like organism. On the other hand, solid types may occasionally be replaced by granular types.

Gorham of Providence, in the examination of 2,375 cultures, about 1,000 of them from healthy subjects, verifies Wesbrook's observations and concludes: (1) That diphtheria-like bacilli are more frequent in the nose than in the throat. (2) That there are diphtheria-like bacilli in the noses and throats of a large percentage of apparently healthy people. (3) That many morphological varieties of the B. diphtheriæ may be recognized. (4) That the change from granular or barred types to solid staining types seems to take place under the influence of the body fluids of a person immune or becoming so. (5) That the virulence of the B. diphtheriæ seems to be correlated with the microscopic form. (6) That the so-called xerosis, pseudodiphtheria or Hofman's bacilli, are morphological varieties of the B. diphtheriæ, sometimes capable of producing clinical diphtheria, but usually non-pathogenic to guinea-pigs. (7) That it is probable that the solid staining types may regain their virulence when they have once lost it.

The relationship of virulent bacilli to non-virulent diphtheria-like bacilli has occupied the attention of investigators since 1887. Dr. Anna W. Williams, as a result of studies in New York City, at the Willard Parker Hospital for contagious diseases, and elsewhere, believes that there are distinct species and sub-species of diphtheria-like bacilli, which have no tendency to become converted one into the other. As many non-virulent diphtheria organisms retain their characteristics under various artificial and natural conditions she thinks that they may be regarded from a public-health standpoint as harmless. She concludes that the morphologically typical diphtheriæ bacillus is a distinct species from the atypical diphtheria-like bacillus and so-called pseudo-forms. Morphologically, the organisms described as pseudodiphtheriæ bacilli have resembled the solid color forms of B. diphtheriæ in Wesbrook's scheme. The so-called xerosis bacilli resemble the barred forms.

A committee of the Massachusetts Association of Boards of Health has endeavored to collect data regarding the occurrence of diphtheria bacilli in well persons. The coöperation of leading bacteriologists, both within and without the State, was secured. A report was given at the April quarterly meeting, 1902. Wesbrook's plates were furnished to all the workers. Cultures were taken from both the nose and throat, amounting to over 4,000 in number. It was found that between one and two per cent. of persons examined in the East were infected with typical diphtheria bacilli of the granular types, of the so-called involution forms of the common long form of diphtheria bacillus, and of the similar but shorter forms. Solid-color types were found in about 26 per cent. of cases in the nose, and in about 5 per cent. of cases in the throat. The results in Minnesota of cultures taken almost altogether from children in institutions where diphtheria had existed from one to eighteen months previously, showed a higher degree of prevalence of all the forms. The committee believes that in healthy persons only the granular types of the forms mentioned above should be considered as diphtheria bacilli. Forty-seven tests of the virulence of granular forms found in throats of healthy people were made. Only about 17 per cent. proved to be virulent.

The committee concludes: (1) It is impracticable to isolate well persons infected with diphtheria bacilli if such persons have not, so far as is known, been recently exposed to the disease. (2) It is not advisable, as a matter of routine, to isolate from the public all the well persons in infected families, schools, and institutions, cultures from whom show the presence of diphtheria bacilli. The committee further believes that the danger from an infected healthy person depends on the age, habits, surroundings, occupation, and intelligence of the individual, and all of these matters should be taken into consideration by the health authorities.

Dr. Laird and his co-workers of the Bender Hygienic Laboratory, Albany, from July, 1901, have been making observations according to Wesbrook's scheme, and found that granular forms were found in more than half of the cases diagnosed as diphtheria. It should also be noted that in cultures for release from quarantine, solid-color forms alone were found in a much larger proportion of cases than in cultures for diagnosis. This confirms the observations of Wesbrook and Gorham, that in the later stages of the disease the granular types are frequently replaced by solid-color types. The solid types have been found to be the only ones present in a considerable number of the clinical cases of diphtheria. This is thought by the committee of the Massachusetts Board of Health to be a very rare condition, but Wesbrook and Gorham have both found them present alone in cases of clinical diphtheria, and have several times isolated solid forms in pure cultures from healthy persons, and proved them virulent to guinea-pigs.

Amyot of Ontario states that the types found in cultures vary with the locality to some extent, and Gorham agrees with this statement, but Laird says there was not a constant difference between the types from Albany and Schenectady, or between types from different parts of New York State.

Preventive Medicine.

General George M. Sternberg contributes to *Popular Science Monthly*, February, an article treating of preventive medicine. He shows that sanitary measures have greatly decreased

within late years both the prevalence and virulence of certain diseases. Referring to typhoid fever and cholera, he notes that, until quite recently, the attention of sanitarians was so firmly fixed upon the demonstrated transmission of cholera and typhoid fever through the agency of contaminated milk or water, that other modes of transmission were overlooked, or at least underrated: For instance, the carrying of these diseases by insects or by air in the form of dust. General Sternberg refers to the fact that, for many years, he has insisted upon the part played by flies as carriers of infectious material from moist masses of excreta from cases of cholera and typhoid fever. Certainly the most fatal disease in armies in the field at the present time is typhoid fever. Our war with Spain and the South-African war showed that; although some advance has been made in preventing this disease, there is yet room for immense improvement. The saddest and even reprehensible feature with regard to the mortality among troops from typhoid fever in these two wars was that much of it was preventable. Insanitary conditions in the camps, and the lack of really good water filters, combined with gross carelessness in many details, owing to the ignorance of the rank and file, and the paucity of proper supervision, were the causes of the high death rate.

Medical officers trained in sanitary matters are badly needed in armies. Experience, however, does not seem to teach wisdom in this respect, for, when a war breaks out, it is not long before typhoid fever begins to claim its victims. This is matter which requires serious consideration, and by the authorities of the army of the United States as much as by any army of the world

Insanity in the German Army.

The inhabitants of Germany and of other countries whose population is of like origin, have always had the reputation of being somewhat predisposed to mental instability. The large number of suicides which occur among these people would seem to show that this belief is not without some foundation. Further evidence has recently been given in support of the view that the Germans are prone to insanity by Assistant-Surgeon E. Stier of the German army, who has just published a pamphlet of forty-three pages on the "Prophylaxis and Treatment of Mental Diseases in the German Army."

The *Lancet*, referring to this pamphlet, says: "Relying upon an extensive examination of the statistics bearing upon his subject, Dr. Stier starts with the disturbing statement that mental affections, properly so called, are increasing not only among the civil population of Germany, but also in the army. In 1882 the number of lunatics in the ranks was 0.32 per 1,000 of strength, whereas in 1898 the proportion was 0.52 per 1,000. Compared with the total sick rate from all causes—682.5 per 1,000 in 1898, the disability from lunacy may seem small, but the above ratios are exclusive of all such affections as epilepsy, hysteria, and chronic alcoholism, in which mental symptoms are secondary. Military surgeons, continues Dr. Stier, have to consider lunacy from three separate points of view: Firstly, as it affects recruits, in order that incipient and obscure cases may be eliminated; secondly, in its latent form among enlisted soldiers, so that possible outbreaks may be foreseen and guarded against; and, thirdly, as an established disease to be treated and subdued. If, he adds, it were possible to recognize all cases of latent or potential insanity among recruits, there would not be many lunatics in the ranks. To this end it has been proposed that experts in mental disease should sit upon all recruiting boards, but to such a proceeding there are objections. For instance, the amount of time necessary for the establishment of accurate diagnosis for every recruit would be prohibitive. A military life, in the writer's opinion, is not entirely exempt from danger to the mental equilibrium of its votaries, but very often when lunacy follows, and appears to depend upon such causes as sunstroke or cranial injury, the probability is that the latter merely acted as an excitant. If the sufferer had been perfectly sound of constitution previously, the upsetting of his mental balance would not have supervened."

After discussing the various causes of insanity to which a soldier, from the nature of his calling, is peculiarly liable, Dr. Stier recommends that in every military station, large or small, there should be a special hospital for insane patients, for the reason that in a general ward lunatics exercise a deplorable effect, and it is impossible to supervise and control them. The writer also suggests that instruction in mental diseases should be made available for military officers.

It would be instructive for purposes of comparison to gather statistics with regard to insanity among the other large European armies. It is possible that mental diseases are as rife among some of these as among the soldiers of Germany. Probably, however, it would be difficult to obtain accurate figures, as no people of the world are as careful and painstaking in collecting reliable information on any subject as are the Germans. Nevertheless, the amount of insanity occurring among the civil population of a country is a good criterion of its prevalence in its army. The whole question of statistics of insanity throughout the world requires more exact attention than has been given to it in the past.

The Food Factor in Education.

"Overpressure" in education has now for some time been made the theme of endless discussion. This crusade against modern methods of training the rising generation has not been undertaken without valid cause. The youth of great cities throughout the world, are crammed with knowledge—much of which is more or less useless—while their physical condition is neglected. The consequence is that the urban population is degenerating in physique and constitution, and is becoming every year less fitted to fight successfully the battle of life. In the *British Medical Journal*, April 4, is an article which, although allowing that the present tendency to overload the minds of the young produces many evil effects, yet contends that insufficient food is a factor of much importance in the production of ill-health. And that the diet of growing children is generally inadequate, both as regards quantity and quality. Dr. Clement Dukes, a distinguished authority on school hygiene, states that the average schoolboy requires meat twice a day, and suggests that the innumerable petty misdemeanors of boys may be due to insufficient nourishment. Underfeeding is especially noticeable in the case of girls. Dr. Newsholme points out that girls thus underfed often get into the habit of relying on bread and butter and puddings, to the almost complete exclusion of meat and other nitrogenous food. The conclusion arrived at from a consideration and comparison of diets in various schools in England and France, is that, as a rule, not enough nitrogenous food is given, and that girls are generally underfed. In these days, when examinations are harder and competition

more acute than ever before, the strain upon the mental faculties and upon the nervous system of those at school and college, is exceptionally severe, and in order to preserve good health, the necessities of the body must be carefully looked after. The young, then, when studying hard should not only be given sufficient food, but suitable food.

State and Schools.

The *Hospital*, January 3, contains an excellent review of the manner in which school inspection is carried on in this country and in Great Britain. It is gratifying to our self-esteem to observe that all the English authorities quoted acknowledge that matters in this respect are managed better on this side, and urge the municipal authorities of British cities to copy American methods.

Newsholme, writing in the *Practitioner*, March, 1902, pays a well-deserved compliment to the superiority of the methods of school inspection prevailing here over those of his own country. He gives an account of the very thorough system which is in force in the schools of Boston, and mentions that the School Board of London has been advertising for nurses, one of whose duties would be the inspection of the school children's heads for ringworm. Lea, writing in *Public Health*, July, 1902, thinks that the school authorities should see that the health of the children does not suffer, and that they should, as far as possible, be protected "from the infectious and loathsome diseases so prevalent in schools." The London School Board hopes that by instructions and pamphlets the teachers themselves will be able to diagnose these complaints. As, however, Lea remarks, this is no part of a teacher's work and would be of comparatively little value. The same writer is also of the opinion that the expense of the introduction of the American system of daily medical inspection of the scholars would be more than balanced by (1) a diminution in the number of cases of infectious diseases, (2) increased school attendance, and (3) improved health of the children. The Manchester School Board estimates that through measles alone the elementary schools of Manchester lose $10,000 per annum.

Collins, also writing in *Public Health*, says that "it is difficult to say how far the State may safely go in relieving the parents of responsibility, but it is quite certain that a child of the slum, half fed, half blind, half deaf, and with only a half-formed physique, is unable to profit to the full extent by the instruction offered by the State. In aggregating children together in school-rooms, it is unavoidable that derangements should occur. Much can be done by building suitable school-houses, providing efficient ventilation and warming, and the provision of out-door covered class-rooms.

Early this year, according to the *British Medical Journal*, the School Board of London appointed eight oculists to pay 200 visits to schools under control of the Board, with the object of testing the vision of the children. A report has been presented of the work done up to the beginning of the summer vacation beginning July 23. Each child, after examination, is presented with a card, to be taken home to the parents, on which advice as to treatment is written when necessary. Serious visual defects were found in 8 per cent. of the boys, and 11 per cent. of the girls. These proportions seemed to be maintained throughout social life. Taking into consideration the various groups of schools, it may be said that the percentage of visual defects varies enormously, being small in the better-class districts and greater among the poor."

Notwithstanding that the United States is, upon the whole, in advance of Great Britain so far as school inspection is concerned, there is yet room for very considerable improvement. In New York City—to which come, and, as a rule, stay, most of the afflicted who managed to evade the port inspectors—school inspection should be especially rigorous. Through laxness of inspection trachoma is said to have spread through all the schools of the East Side. It is a paramount duty of municipal authorities and health boards to see that children in schools are not suffering from any complaint which might spread among their fellows.

The Epidemic of Cerebrospinal Meningitis at Lisbon.

Mr. H. W. Seager writes in the *Lancet* of November 1 on the experience he gained from the study of this disease during the recent epidemic in Lisbon. He says in part "Cerebrospinal meningitis is a disease almost entirely confined to the lower classes, so that probably dirt, overcrowding, and malnutrition are largely conducive to its prevalence in Lisbon. It appears to be infectious, and to a slight extent contagious. A plan of Lisbon, in which the infected localities are marked, shows large areas of houses and offices occupied by the wealthier classes quite free from this disease, while numerous cases occur in the poorer districts surrounding these areas. The disease appears to have no connection with the water supply or sewage."

The writer says that a very remarkable symptom of the disease is the abolition of all reflex action in the quite early stages; abdominal reflex action may be exaggerated, but disappears in a day or two. "The patellar reflex action not only disappears, but when the patient is turned on one side, or raised to a sitting position, the knees are so forcibly flexed that it requires considerable strength to straighten them. This state begins on the third day of the disease, and continues for fully eight days after convalescence, but the other reflex actions return earlier. The eyeball may be touched during the height of the disease, with no consciousness on the part of the patient. Herpes labialis is common among these cases, and is looked upon as a favorable sign; phlyctenulæ are rare. Delirium commonly occurs, even on the first day, and lasts for three or four days. Hemorrhagic nephritis occurs in very many cases, and lasts for three or four days. Paralysis of the bladder also occurs frequently, but is quite independent of the nephritis. Gastric hemorrhage is almost always present, and vomiting is an early symptom, especially in relapses. Various forms of paralysis often complicate this disease, and sometimes prove incurable. Other complications and sequelæ are corneal ulcers, blindness from atrophy of the optic nerve, suppurative otitis of the middle ear, bronchopneumonia, pulmonary congestion, and hemorrhage, with very low temperature, and even with no fever. These lung troubles do not always cause death, which is usually the result of myocarditis—a very serious complication. The liver is enlarged and swollen, and very tender, and projects sometimes three or four centimeters beyond the ribs. In these cases yellow blotches appear on the skin, and after death necrosed patches are found on the liver."

Although the foregoing clinical picture of cerebrospinal meningitis is vivid, and in the main agrees with the observations of those medical men who have come in contact with the disease, yet the pith

of Mr. Seager's paper is contained in that portion which deals with the treatment.

He says, concerning the treatment with injections of lysol, that of thirty-one patients thus treated thirteen died, and the eighteen who have recovered are completely cured. The early treatment, he further remarks, was by hot baths and ice to the head; under this régime 60 per cent. died. Then simple puncture of the spinal cord was tried in twenty cases, in three of which the liquid was already purulent. Of these twenty patients, nine died, and of the eleven who recovered, one was deaf, one had persistent paralysis of the left arm, and four had bed-sores. The next seven cases were treated by puncture and removal of the fluid and an injection of oxycyanide of mercury. Of these seven patients four died and three were cured. The fluid was found to be purulent in five of the cases, four of which proved fatal.

Drs. Franca and Silva Carvalho introduced treatment by lysol injections, and Dr. Franca has further proposed to aspirate the ventricles and to withdraw the fluid which, if allowed to remain, is certain to cause a speedy and painful death.

It would seem from these results that injections of lysol after puncture and aspiration have a beneficial effect on the course of the disease. Drs. Franca and Silva Carvalho also agree that in spite of the assertions of the French observers, meningococci are absolutely typical of the disease.

News of the Week.

Beth Israel Hospital.—At a meeting of the Board of Directors of this hospital, held May 28, the following were unanimously appointed as members of the Medical Visiting Staff of the hospital: Drs. Fred Walker Gwyer, visiting surgeon; Max Einhorn, visiting physician; Henry Koplik, visiting physician to the children's service; A. Hymanson and J. Barsky, adjunct visiting physician to the children's service.

Dinner to Mr. Moynihan.—Mr. G. B. A. Moynihan of Leeds was given a farewell dinner at the University Club by Dr. William B. Coley on May 26. Among those present were Drs. William T. Bull, George Ben Johnston of Richmond, V. P. Gibney, Walter P. Jones, George Woolsey, Charles N. Dowd, Joseph A. Blake, B. Farquhar Curtis, and John B. Walker.

The New York State Pharmaceutical Association will hold its annual meeting in Utica on June 16, 17, 18, and 19. It is expected that about five hundred delegates will attend the meeting. Mr. William C. Anderson of Brooklyn is a candidate for the presidency of the association, and as he has the backing of practically all the New York City members, it is believed he will be elected. Mr. Thomas Stoddart of Buffalo is now serving his second term as president. The candidates for appointment to the State Board of Pharmacy are Charles Sears of Auburn, and John Hurley of Little Falls. There will be a number of receptions on the opening day of the convention, and the local committee has arranged a series of trolley rides. There are about one hundred miles of track in and about Utica, running to the most picturesque parts of the Mohawk Valley. During the sessions of the convention there will be reports of the committee on new remedies, legislation, State Board of Pharmacy, trade interests, adulterations, and various other subjects.

A New Bellevue Hospital Site.—The New York City Board of Estimate recently held a public hearing on the plan of the trustees of Bellevue and allied hospitals to acquire the block bounded by Twenty-eighth and Twenty-ninth streets, First avenue and the East River, for a site for a new hospital. The assessed value of the land in the block is $846,000. A number of physicians spoke in favor of the plan, but the matter was finally referred to the Comptroller for further investigation.

The Harlem Hospital.—A three-story dwelling house on One Hundred and Twentieth street has recently been purchased for use as an addition to relieve the overcrowding of the Harlem Hospital. It will be renovated and made available for hospital and dispensary purposes.

Proposed Sanatoria at Colorado Springs.—An effort is being made to raise funds to build two sanatoria for consumptives at Colorado Springs, one for patients who are able to pay for treatment and the other for poor people. The income from the sanitarium for the well-to-do patients will, it is expected, pay for the running expenses of the other besides its own expenses. Each institution will cost, it is estimated about $200,000.

A Case of Laboratory Plague in Berlin.—Dr. Milan Sachs, a young Viennese physician, died last week from plague in Berlin. He had studied the disease at Agram and other Balkan cities, and came to Berlin a few weeks ago to continue his researches at the Bacteriological Institute, where he became infected with the plague. He was transferred to an isolated barrack, where he died June 5. One of the attendants of Dr. Sachs is also ill, and it is believed that he also has contracted the plague. The authorities have adopted rigorous measures to prevent a spread of the plague. All the household effects of the family with which Dr. Sachs boarded have been confiscated and burned, and all persons who came in contact with the dead man have been segregated for observation. In consequence of this death the Government has decided to issue a decree forbidding further experiments with plague germs, the risk of sperading infection being considered more dangerous to the public health than the knowledge gained in studying the deadly microbes justifies. The decree forbidding further experiments was determined upon at a conference at the Ministry of Education of the sanitary and police authorities, in which the Emperor's physician, Dr. Leuthold, Professor Renvers, and other noted specialists participated. Dr. Sachs was sent to Berlin by the Austrian Government, which intended to use his services in perfecting the sanitary arrangements in Bukovina.

Disease Germs as Weapons in Warfare.—It is reported by way of London that the Macedonian revolutionary leaders have obtained possession of a large quantity of plague bacilli, with which they threaten to cause an outbreak of the plague in Constantinople and Salonica if their demands for autonomy are not conceded. This may be true and may not, but the danger to Europe is probably not great. The report recalls the alleged attempt,forty years ago, to introduce yellow fever into New York and Philadelphia by means of infected clothing. We now know, thanks to the work of the late Major Walter Reed and his associates, that this nefarious scheme would have failed, since the virus of the disease is not conveyed in clothing soiled with discharges from yellow-fever subjects. It is probable that the attempts of the Macedonian leaders would also be foiled by their ignorance of the conditions favorable to the spread of plague, or

quite certainly by the repressive measures which would be taken by the sanitary authorities were the disease to disclose itself.

Yellow Fever is reported to be prevalent in Yucatan. Some apprehension has been created by the appearance of a disease in Caracas which it is feared may be yellow fever. The United States Consul at La Guayra has cabled to Washington that the physicians, while undecided as to the true nature of the prevailing disease, are agreed in believing that it is not yellow fever.

Scarcity of Cod-liver Oil.—The London correspondent of *The Sun* says that, owing to the failure of the fishery catch on the coast of Norway, the price of the best cod-liver oil has risen enormously. Eight gallons now cost 25 shillings. A year ago the same quantity could have been bought for 5 shillings or less. It is stated that several London hospitals now decline to supply their patients with the genuine article, and it is rumored that inferior substitutes, such as shark oil, are employed. The failure of the supply is due less to a scarcity of the fish than to the condition they are in when caught, with their shrunken livers yielding merely a fraction of the normal amount of oil. It is thought this has been caused by the failure of their food supply and the attack on them by seals.

The Christian Hospital of Chicago has come to grief through the employment of very unchristian methods of making money. It plagiarized the old scheme worked some time ago by St. Luke's Hospital of Niles, Mich., of electing physicians throughout the country to membership on the hospital staff. The destined victims were notified of their election and were requested to send a sum of money to pay for the diplomas of membership. For $25, the maximum fee, the applicant received a "beautifully engrossed certificate, which imparts confidence to patients," while for other sums the institution retailed "official buttons" and other insignia intended to impress the credulous. On these diplomas the name of Dr. John B. Murphy appeared as one of the directing physicians, and it was through the suit brought to restrain the hospital from using this name that the scheme suffered the blight of publicity. First the court enjoined the hospital from advertising Dr. John B. Murphy as president of its staff. Then Post-office Inspector Stuart arrested the principal directors of the institution, charging them with fraudulent use of the mails, and the Chicago Medical Society has been collecting additional evidence designed to expose the extent to which the hospital has carried on its operations. The federal grand jury will investigate the charges.

A New Antituberculosis Serum.—A report of researches made during a year and a half with a serum to cure tuberculosis was recently presented to the Newark Board of Health. The report is said to have been so favorable that the board will ask the Newark Common Council at its next meeting to appropriate a considerable sum to enable it to fight the growth of tuberculosis with the serum.

A Vanderbilt Hospital in Paris.—It is reported in one of the London papers that Mr. W. K. Vanderbilt, Sr., has offered to his bride the money to carry out her long unfulfilled desire to build a hospital in Paris for free treatment of the poor. The building will be the most complete that can be devised and thoroughly modern in construction. Mrs. Vanderbilt will have carte blanche in everything relating to the situation and management of the hospital, which will be called by her name.

Conference of State and National Health Authorities.—The first annual conference of the State and national public health officers, for which a call was recently issued by Surgeon-General Wyman, in accordance with the provisions of an act of Congress approved July 1, 1902, met at the new Willard Hotel, Washington, on June 3. The boards of health of various States were represented. The conference was presided over by General Wyman, and after the meeting was called to order Assistant Secretary of the Treasury Armstrong, on behalf of the government, welcomed the delegates and assured them that everything would be done to make their stay as pleasant and profitable as possible. He said that in the great work of improving the health conditions of the country coöperation between the States and between the States and nation was the secret of success, and he promised, in the name of the national government, to do everything to further this end. Surgeon-General Wyman, delivered the opening address (see p. 933). Dr. Foster of California gave a description of quarantine operations in that State, particularly in relation to the plague danger in San Francisco. He said that with the vigorous cleaning out of Chinatown the fear of another attack of this disease was rapidly disappearing. He attributed the success achieved to the hearty coöperation existing between the city, State, and national health officers in endeavoring to stamp out the infection. Dr. Foster was followed in interesting talks by Drs. Townsend, Porter, Egan, Conniff, Bailey, Souchon, Young, Fulton, Baker, and Woodward. At the suggestion of Dr. J. Y. Porter of Florida, a telegram was addressed to the Florida Legislature expressing the hope of the conference that the act now pending before that body providing for the collection of vital statistics would receive favorable action.

At the afternoon session the discussion of local health and quarantine conditions was continued, each representative explaining the sanitary laws and the method of carrying them out in his particular State, addresses being made by Drs. Wesbrook, Hunter, McAlester, Probst, Smith, Lee, Swarts, Simons, Tabor, and Cooper.

The conference adopted the following resolutions:

Whereas, The conference of the State Boards of Health of the United States with the Public Health and Marine-Hospital Service, having confidence in the earnest efforts and ability of the Governor and State Board of Health of the State of California acting in harmony with the Bureau of Public Health and Marine-Hospital Service to thoroughly eradicate bubonic plague heretofore existing in the City of San Francisco, do resolve that in the judgment of this conference, so long as the present effective work is continued, there is no need for quarantine restrictions of travel or traffic to or from that State.

Resolved, That the methods of coöperation between national and State health authorities suggested by the presiding officer, meets the approval of the conference.

A committee was also appointed to draft a resolution expressing regret at the death of Dr. Mathew Gardner, late President of the State Board of Health.

The various States were represented by the following delegates: California, Dr. N. K. Foster; Connecticut, Dr. J. H. Townsend; Delaware, Dr. E. W. Cooper and Dr. Alex. Lowber; Florida, Dr. J. Y. Porter; Illinois, Dr. J. A. Egan; Iowa, Dr. R. E. Conniff; Kentucky, Dr. William Bailey;

Louisiana, Dr. Edmond Souchon; Maine, Dr. A. G. Young; Maryland, Dr. J. S. Fulton; Michigan, Dr. H. B. Baker; Minnesota, Dr. F. F. Wesbrook; Mississippi, Dr. J. F. Hunter; Missouri; Dr. A. W. McAlester; Ohio, Dr. C. O. Probst; Oregon Dr. Andrew C. Smith; Pennsylvania, Dr. Benjamin Lee; Rhode Island, Dr. G. T. Swarts; South Carolina, Dr. T. Grange Simons; Texas, Dr. George R. Tabor; Utah, Dr. T. B. Beatty; West Virginia, Dr. Samuel F. Myers; District of Columbia, Dr. William C. Woodward.

Precautions against Tuberculosis in California.—At the last session of the Medical Society of the State of California, the following committee was appointed to investigate the prevalence of tuberculosis in that State, and to make such recommendations to the society at its next meeting as they may deem appropriate: Dr. F. M. Pottenger, Los Angeles, Chairman; Geo. L. Cole, Los Angeles; Jno. C. King, Banning; Geo. H. Evans, San Francisco, and Edward von Adelung, Oakland, Secretary.

Philadelphia County Medical Society.—At a stated meeting, held May 27, Dr. Burton K. Chance read a paper entitled "A Report of Two Cases of Orbital Cellulitis as a Sequel of Scarlatina," and Dr. George Erety Shoemaker read a paper entitled "The Management of Malignant Disease of the Uterus."

College of Physicians of Philadelphia.—At a special meeting, held May 29, it was decided to purchase for $80,000 a lot of ground 80 by 130 feet on Twenty-second Street below Market for the purpose of erecting thereon a new and commodious building adequate to the increasing needs of the institution.

The West Virginia State Medical Association held its thirty-sixth annual meeting on the 26th, 27th, and 28th of May, 1903, in Glenwood City Hall, Charleston, W. Va., President H. B. Stout of Parkersburg in the chair. The President's Annual Address contained many suggestions of great importance to the moral and material welfare of the association and will go down to the history of the association as one of the most practical and most useful presidential addresses. The secretary's report showed the association to be in a prosperous condition and showed clearly that the great strides it has made during the past year were made possible by its partial reorganization at the last meeting. The report closed with the recommendation that the association undertake to protect its members in suits of mal practice. The association acted upon this recommendation and adopted the following resolution: "That this association pledges its moral support and will substantially defend any member who shall be sued; and further pledges the services of any and all its members when called upon to attend any trial and testify in behalf of the member sued."

The following papers were read and discussed: "The Organization of the Medical Profession," by J. N. McCormack, Bowling Green, Ky.; "The Constitution and By-laws, with Some Comments and Suggestions," by Wm. W. Golden, Elkins; "Puerperal Eclampsia," by E. T. W. Hall, Weston; "The Present Status of Serum and Organotherapy," by J. M. Sites, Martinsburg; "The Promising Outlook Along Electrotheropeutic Lines," by T. L. Barber, Charleston. Symposium on Quarantine: "The Microbiology of the Common Communicable Diseases," by J. Schwinn, Wheeling; "The Etiology of the Common Communicable Diseases, with Especial Reference to the Common Methods of Communication," by A. G. Staunton, Charleston; "The Management of the Common Communicable Diseases, with Especial Reference to Public Safety," by S. L. Jepson, Wheeling; "The Public and the Physician in Relation to the Common Communicable Diseases," by J. C. Irons, Elkins. Dr. T. L. Barber to open discussion with an illustrated paper on "Uniform Signals of Contagious Disease for State and Nation." "Collapse and Shock," by W. S. Keever, Parkersburg; "Mastoiditis," by T. V. Churchman, Charleston; "Demonstrations of the Value to the Physician of Modern Methods of Diagnosis," by A. Rose, Hinton; "The Country Practitioner and What He Can Do for His Patients as a Specialist," by Jno. R. Cook, Fairmont; "Distocia and Its Treatment," by W. H. Sharp, Parkersburg.

At its last meeting at Parkersburg, W. Va., the association adopted, with certain modifications, the Constitution and By-laws recommended by the American Medical Association for State Societies. One of these modifications was the omission of the house-of-delegate feature, an account of the very small number of the county societies then in existence and the lack of self-confidence to be able to organize many such societies before many years. The efforts in this direction during the past year, however, have proven very successful, and encouraged the association to adopt the delegate system for the next meeting, thus making its reorganization complete. To Dr. J. N. McCormack much credit is due for valuable assistance in this matter.

The following officers were elected: *President*, Dr. T. L. Barber, Charleston; *First Vice-President*, Thomas M. Hood, Clarksburg; *Second Vice-President*, Dr. E. T. W. Hall, Freemansburg; *Third Vice-President*, Dr. Rolla Camden, Parkersburg; *Secretary*, Dr. Wm. W. Golden, Elkins; *Treasurer*, V. T. Churchman, Charleston; *Councillors*, C. A. Wingerter, Wheeling; J. W. McDonald, Fairmont; C. S. Hoffman, Keyser; W. H. Proudfoot, Rowelsburg; W. W. Tompkins, Charleston; O. O. Cooper, Hinton; W. S. Keever and H. B. Stout, Parkersburg, and C. R. Enslow and T. W. Moor, Huntington. *Delegates to the American Medical Association*, S. L. Jepson, Wheeling, and W. H. Sharp, Parkersburg. Fairmont was chosen as the next place of meeting.

Pathological Society of Philadelphia.—At a stated meeting, held May 28, Drs. D. L. Edsall and C. W. Miller read a paper entitled "The Calcium Phosphorus and Nitrogen Metabolism in Acromegaly." Drs. Geo. C. Stout and Herbert Fox presented a communication entitled "A Case of Cerebral Abscess." The patient was a child who had complained of pain, together with a bad odor from the ear, without discharge. Eventually the mastoid was opened, and later the brain also, but the pus was not reached. After death an abscess of considerable size was found involving the frontal and temporal lobes. Dr. A. G. Ellis read a paper entitled "Evolution of Scirrhous Carcinoma from Cystic Disease of the Mamma," and he reported an illustrative case and exhibited the specimens. Dr. Ellis read also a paper entitled "Hemorrhagic Gastritis Due to Pyloric Lodgment of a Swallowed Laryngeal Membrane." Dr. M. Howard Fussell presented a specimen of aneurysm of the aorta rupturing into the œsophagus. The patient had been a man who had vomited blood only a short time before death, which was found to be due to rupture of an aneurysm of the descending aorta. The sac had formed between the aorta and the œsophagus, and the latter was the seat of a perforation of considerable size, largely plugged by blood-clot. Dr. Randle C. Rosenberger presented specimens of

adrenals containing liver-like cells; teratological form of the tænia saginata; an appendix with two lumina; and an adult heart with a bifid apex. Dr. Brooke Anspach presented a specimen of ovarian dermoid containing thyroid-gland tissue.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

JUBILEE NURSES—GENERAL MEDICAL COUNCIL—ETHICS OF OPERATIONS—RHEUMATIC IRITIS—DIFFERENTIATION OF TROPICAL FEVERS—EATING HAIR—MENINGOMYELOCELE—ANGIOMA OF SYNOVIAL MEMBRANE—LEPROSY—ROYAL SOCIETY—BUST OF SIR W. MAC CORMAC—DEATH OF LLOYD ROBERTS.

LONDON, May 22, 1903.

YESTERDAY afternoon the King and Queen received a deputation from the committee of the Women's Memorial to Queen Victoria. This consists of a substantial sum to form an endowment fund for the Queen's Jubilee Nurses Institute. You will, doubtless, remember that the late Queen gave £70,000 of the Jubilee Women's offering to establish that institute for district nurses. It has been a great success, and many poor patients have reason to bless the Jubilee Nurses.

To perpetuate the memory of the late Queen, this women's collection has been equally successful—about £66,000 being raised in England and Wales, £6,000 in Ireland, and £12,000 in Scotland.

The King, in thanking the deputation, mentioned the additional pleasure it gave to the Queen and himself that it was subscribed as a memorial of his beloved mother Queen Alexandra, as patron of the Queen's Nurses, also briefly expressed thanks.

The General Medical Council met yesterday for its seventy-sixth session when the president, Sir W. Turner, delivered another of his introductory addresses. In it he referred to the efforts made to augment the income of the council, and said a memorandum had been prepared as a basis of a memorial to the Privy Council. Some of us think the council ought to restrict its expenditures, but it continues to follow the example of too many public bodies. He said information had been received from which it seemed that one of the provinces of Canada was unwilling to renounce its right of independent registration, but until that was done the Dominion could not enjoy reciprocity with this country. This appears to be an affair of Canadian practitioners, and like other points unnecessary to occupy the time of the Council, and so increase its expense. The penal cases to be considered are numerous and important.

The oration of the Medical Society was delivered on Monday, by Sir W. H. Bennett, who devoted it to some reflections, mainly ethical, on surgical operations. The thought that at the present day there was sometimes too much readiness to operate, and too little consideration of the ultimate benefit to the patient. No operation could be said to be absolutely safe. That a patient would be sure to die if left alone was not, in itself, sufficient reason for operating. The interests of the patient are the first consideration. Exploratory operations are not to be undertaken as a routine procedure; indeed, all routine in surgery is to be strongly condemned—applied to a particular disease it increases the danger. Judgment is the enemy of routine. Judgment as to the end of operations was really more important than skill in performing them. A conversazione followed the oration.

In writing last week about rheumatic affections I exhausted my space before referring to some experiments on rheumatic iritis which I think worth your notice. It must be admitted that iritis is a very rare complication of true rheumatism—so rare that many refuse to recognize it as such and would regard any case as accidental; or, perhaps, gonorrhœal rather than rheumatic.

Drs. A. Paine and F. J. Poynton, whose other researches on rheumatism I have reported, have, however, communicated to the Ophthalmological Society the experiments mentioned above, which tend to support the view that iritis coming on in acute rheumatism is due to their microbe. The diplococcus developes in the tissues and cells rather than in the exudation, so that it is hardly possible to identify it in fluid from the anterior chamber, and the complication is too rare to furnish an opportunity of examining the inflamed iris itself during the fever. Experiments on rabbits were, therefore, made, and the results exhibited to the society and shown in lantern slides. The specimens of iris showed diplococci *in situ*, the distribution resembling that of the organisms found in the synovial membranes of acute rheumatism. Dr. Poynton said that the ordinary methods of preparation and staining sufficed for the detection of the microbes when present, as the subsidence of the inflammation was due to their destruction or reduction to a latent state, he would not expect to find them in portions of iris removed during the quiescent period.

The differentiation of some tropical fevers was the subject of the paper at the Medico-Chirurgical Society last week, by Captain L. Rogers, M.D., I.M.S. He dealt with some 200 fevers in the Calcutta hospitals during the past two years. Serum tests, leucocyte counts, clinical notes, and temperature charts were given. These confirmed former cases which he had recorded. In fifty consecutive cases of typhoid fever there was frequently an increased percentage of lymphocytes without any increase of mononuclear white corpuscles, except during convalescence, or when the case was complicated with malaria. Captain Rogers found typhoid, as determined by the serum test, rather frequent in natives, and in this opposed to Dr. Crombie's experience, as mentioned at the Indian Medical Congress, 1894. Another series of cases went to show the value of the large mononuclear increase in malarial remittent fevers. Captain Rogers concluded that the simple continued fevers met with were malarial, and that Crombie's "non-malarial remittent"—seen almost exclusively in natives—was in reality typhoid.

Dr. Manson thought the conclusions offered were not justified, for increase of large mononuclear leucocytes occurred in other diseases than malaria. Observations in Calcutta could not be applied to African fevers. He held there were many continued fevers that were neither malarial nor typhoid.

Dr. A. E. Wright also objected to the conclusions of the paper, as well as to the method employed. We had no definite list of size of mononuclears, and the pressure of a cover-slip might easily alter a cell. Malaria was probably rather rare in Calcutta.

Dr. G. C. Low admitted that an increase of large mononuclear leucocytes occurred in malaria, but held that this was not sufficient for diagnosis.

One of those curious cases of eating hair was related at the Clinical Society by Mr. C. A. Morton, whose patient was a young woman of eighteen years. A very hard abdominal swelling, freely movable and resonant, with pain and vomiting almost suggested an omental tuberculous mass or some growth. On operation the hair ball was removed and weighed one and three-quarters pounds. Afterward a history of eating hair was obtained. Wm. Paton mentioned a case in a child of nine years, also removed by operation.

Mr. H. B. Robinson showed a specimen of spinal meningomyelocele removed from a girl of eleven months. Abdominal section had been done and a cyst found which was emptied, and the sac, which was firmly adherent to the spine, ligatured and cut away. The child died ten days afterward. At the post-mortem various abnormalities were found. A similar specimen from the Hunterian Museum was shown.

Mr. F. S. Eve read a paper on angioma of synovial membrane and of muscle. He related four cases, all occurring between the ages of ten and twenty-five years. Some complained of symptoms suggestive of tuberculosis, others had wasting of muscle. Two of the cases were of special interest, as the angioma was entirely confined to the synovial membrane, which seems to be a very rare condition, no record of it being known. Campbell de Morgan, in 1864, collected the muscular cases recorded up to that date in his article in the *British and Foreign Medico-Chirurgical Review*. In none of them was a joint or synovial membrane involved. Some were well-defined and encapsuled, others diffuse. In one pulsation was observed, in some blood could be expressed from the swelling; some were mistaken for lipoma.

Mr. Eve remarked that cases involving the synovial membrane may not really be so rare, for besides the four related he had seen two others, and probably they would have remained unrecognized but for the advances in surgery, which have enabled us to open joints with impunity.

The president, Mr. Howard Marsh, said he had never met with cases precisely similar. He suggested that these swellings might become inflamed and so resemble active, tuberculous disease. He mentioned one case in which there was pulsation leading to a question of aneurysm, but the pulsation was variable, and under an anæsthetic disappeared, so was probably a cavernous angioma of muscle. Other speakers mentioned cases in muscle, but no one had met with it in synovial membrane.

You know that Mr Jonathon Hutchinson went to India to look into the evidence there as to the cause of leprosy. He has returned as firmly convinced as before of the truth of his "fish theory," and last week gave a lecture on the subject at the Polyclinic. He thinks that recently "out-and-out contagionists" have diminished in number, and that those who agree with him correspondingly increased. At the Tau Turan asylum in the Punjab, the Hindus and

Mohammedans contribute 127 lepers from a population of 27,000,000, while 38.000 native Christians furnish 34. In Calcutta the native Christians are 1 per cent. of the population, but have more lepers than the Mohammedans, who are thirty-two times more numerous, and half as many as the Hindus who are sixty-two times as numerous. Mr. Hutchinson sees no other conclusion than that change to Christian food by the poorer natives is most powerfully productive of leprosy. Sir W. Broadbent declared he had listened to the lecture with an interest approaching conviction.

There was a brilliant assembly at the Royal Society's *conversazione*. The principal attraction was the demonstration of the properties of radium by Sir Wm. Crookes.

The College of Surgeons has accepted a replica of the bust of Sir Wm. MacCormac which has been executed for St. Thomas's Hospital.

Dr. E. Lloyd Birkett died on the 8th inst., full of days and full of honors. He was born in 1814, graduated at Cambridge in 1838, retired from practice in 1890. He was for some years editor of *Guy's Hospital Reports*, and he filled various offices at the College of Physicians, up to the vice-presidency.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE MANILA WATER-SUPPLY—THE MATERNITY HOSPITAL—ISOLATION HOSPITAL FOR THE CHINESE—THE CHOLERA.

MANILA, March 15, 1903.

REQUEST has been made by the natives living in the valley of the Mariquina river, from which the water supply of Manila is obtained, that the present sanitary cordon around the river be withdrawn and that they be given access to it. At present the watershed is carefully guarded by American soldiers, and pollution of the river prevented as far as possible. The natives argue that as cholera no longer exists in the valley there is no reason why they should not be allowed to use the stream as they had previously been in the habit of doing. The careful quarantine of the Mariquina valley is undoubtedly the reason why Manila has practically been exempt from cholera for the past four months, and with cholera existing at a large number of points in the islands there is no possibility that the request for the removal of this quarantine will be entertained for a moment by the health authorities. The quarantine of the river was removed for a short time last November, but this action was followed by an alarming increase in the number of cholera cases in Manila, and the quarantine was promptly re-established, with an immediate reduction in the cholera mortality of the city. It is probable that, under present conditions, the quarantine will be relaxed to the extent of allowing the natives to draw water from the river and cross it in boats, as deprivation of these privileges is working serious hardship to those living in the valley, and the policy of the Civil Government is not to excite dissatisfaction among the natives where it can possibly be avoided. In the Philippine Islands, at the present time, the relation of sanitary procedures to political considerations has to be carefully considered, and the sanitary problems are not as simple as they would be if an intelligent and sympathetic population could be counted on for assistance, and such support in public health matters as is given by the citizens of communities in the United States.

The water supply of Manila offers one of the most urgent sanitary problems at the present time. In quantity it is insufficient for the existing population of the city, allowing only about 10,000,000 gallons daily, or a total of about 30 gallons per capita for all purposes. The mains are so small and the reservoir at such slight elevation that the pressure is insufficient to force water to the second stories of buildings in many parts of the town during business hours, even when the pumps are run to their full capacity. With the rapid enlargement of the city which is going on under the stimulus of increased business due to American control of affairs, and particularly when a proper sewerage system for the city is installed, the amount of water necessary for city uses will have to be doubled. Such an increased amount will mean practically the entire flow of the Mariquina river at the dry season. At present, a flimsy dirt dam, liable to be washed out at any time by a sudden flood, forms a small pond from which the water is pumped by four engines, of obsolete type, to the top of a hill, about 140 feet high, whence it runs by gravity into a reservoir at El Deposito, where a certain amount of purification by sedimentation is accomplished. In the dry season these four engines are just capable of satisfying the city's needs, and if one or two of them should be crippled for any length of time a water famine in Manila would result. The reservoir at El Deposito holds a supply for about thirty-six hours only, an amount quite insufficient to tide over even an ordinary emergency. The Deposito reservoir is divided into two parts to permit of alternate cleaning; it consists of a large number of connected vaults hewn out of the solid rock and arched over with masonry, on a hill about 65 feet higher than the level of Manila. The water is carried into the city from the reservoir by gravity, being taken over the intervening four miles through a large pipe laid on the surface of the ground. In character, the water supply of Manila is not at all satisfactory, as at present some 20,000 natives live on the Mariquina watershed above the intake for the pumping station, and the town of Mariquina, directly on the river banks, is only about a mile and a half from this pumping station. Under such conditions absolute freedom from contamination cannot be secured even by the most strict quarantine measures, especially during the rains. The government is fully alive to the necessity of providing a more abundant and purer water supply, and a corps of engineers is engaged in drawing plans and making up estimates for this purpose. At the head of the Mariquina valley, some fourteen miles from Manila, the water comes clear and undefiled from the mountain gorges, draining a watershed which is uninhabited, and, the most of the proposed plans contemplate the drawing of water from this source. One tentative proposition is to erect a dam at the head of the valley, and carry the water into Manila by gravity, or, if the latter be not possible, to erect a pumping-station at the dam. Levels are now being run to decide this question. If a pumping station is necessary, the cost of the undertaking will be vastly increased, as the proposed dam site lies almost in a wilderness, with practically no road facilities, and it would probably be necessary to run a fourteen-mile spur of railroad out from Manila, for the transportation of machinery, material, and coal. Should this plan be decided on, the present pumping-station, conduit system, and reservoir would be held in reserve. Another plan contemplates piping water down to the present pumping station, remodelling the latter, and continuing its operation. Against this is the fact that the present reservoir at Deposito and the water conduits are too small, and must be greatly enlarged, or new ones constructed. This scheme would probably never be satisfactory, and entails the hauling of a vast amount of coal by carabao carts, over several high hills, a bad road, and some eight miles of distance from the Manila docks. A system of supply by gravity, direct from the mountains, would be expensive at the outset, but more economical and satisfactory in the long run. A filter bed for sand filtration, in connection with the new system, would be desirable, but in view of the original purity of the water at its proposed source, the cost of construction and maintenance of such a filter bed and the great desirability of at present using any available funds only for the most necessary objects, such a filtration plant will probably not now be considered in connection with present plans. It is understood that the commission stands ready to issue bonds for the city of Manila, to the extent of $4,000,000, for the construction of the new water-works. Of course with the large increase in the quantity of water supplied, better facilities for the removal of waste waters will be more imperatively demanded and the construction of a municipal sewerage system will probably be carried on at the same time.

Mention was made some time since of the financial straits in which the Asilo de Maternidad, or Maternity Hospital of Manila, found itself, and of the special effort being made to secure the funds necessary for its continuance. The committee charged with the duty of securing subscriptions has not met with much success, and the managing board has consequently decided that the hospital must be closed. The children now in the asylum will be provided for, as several prominent Filipinos have agreed to take them into their own households.

The Chinese Chamber of Commerce of Manila, which has great influence over the Chinese here, has recently decided to build a retention camp and hospital buildings for the treatment of plague, cholera, and smallpox among the Chinese. A sufficient sum of money will be expended by them properly to construct and equip these buildings according to the ideas of the board of health. These hospitals for epidemic disease will be located near to the Chinese general hospital for purposes of administration. Up to the present time all Chinese plague, cholera, and smallpox cases and contacts have been sent to the general city contagious disease hospital and detention camp, an arrangement which did not meet with the approval of the Celestial, who prefers strongly not to be separated from his own kind, and is willing to construct and maintain his own hospitals to secure this result. At a recent meeting of the influential Chinamen here, it was decided by them to expend any necessary sum to improve the sanitary condition of the Chinese districts of Manila, they appreciating that plague is far more prevalent among the Chinese than the other classes here, and that their

commercial interests are suffering accordingly The Chinese Chamber of Commerce is supporting the board of health work probably more for commercial than humanitarian reasons—but whatever the reason, its support is of great value, and the Chinese here are more amenable to sanitary control than are the Filipinos.

Cholera still exists at a number of points in the islands, furnishing a large number of foci from which it may spread with the beginning of the rains. It is present in the reconcentration camps in the southern part of Luzon, where the native troops are engaged in hunting down the bands of ladrones which still exist there. In one day reports showed the presence of the disease in Luzon, Samar, Negros, Leyte, Mindanao, Romblon, and several of the smaller islands. Except in Mindanao, the number of cases are few, and are of importance merely as showing the persistence of the infection. In Mindanao, particularly on the south and east coasts, a number of cases have occurred among the American troops engaged with the hostile Moros. During active operations in an infected region, the absolute protection of the troops engaged is not possible. What the extent of the disease is among the Moros is not known, but it is undoubtedly considerable. Every now and then the death of some hostile Moro chief, from this disease, is reported, and the officer in charge of the present military operations is said to have stated that there was more to be feared from cholera than from the Moros. Several cases of cholera have lately occurred on boats returning from the southern islands to Manila, but the infection has so far been kept out of the city from this source through the vessels being intercepted and sent to the Mariveles quarantine station.

MOSQUITOS, QUARANTINE, ETC.

A REPLY TO DR. E. SOUCHON.

To the Editor of the Medical Record:

Sir: Published in the Medical Record of April 18 there appears a reply by Dr. Souchon to my article of March 14 in critical response to the Doctor's statistics and conclusions concerning the history of yellow fever in New Orleans. The statistical table and the deductions drawn therefrom are contained in a contribution to the Medical Record, published October 25, 1902, entitled "On the Eradication of Yellow Fever in Havana."

While a difference of opinion between individuals is of small consequence, ordinarily, and of little general interest, a divergence of view between public officials regarding the application of measures preventive of disease is of great importance and much concern, especially to those who may be affected by the disease to be prevented; and, while it is a matter of small moment that Dr. Souchon, or Dr. Kohnke is right or wrong, the correctness of historical records is a matter of sufficient import to warrant discussion of the subject.

I beg, therefore, the privilege of making reply through your columns to Dr. Souchon's estimate of my observations.

I thought I had made myself very clear as to the reasons which prompted me to question the correctness of the Doctor's conclusions.

When I wrote "I differ widely from him in his main contention, that quarantine against yellow fever need not consider the mosquito," I announced my dissent from his opinion; and when in the next paragraph I wrote "the *achieving* result has *always* been the excluding of infected mosquitos," I expressed my own.

Dr. Souchon says in his reply: "I do not say in my paper that quarantine against yellow fever need not consider the mosquito."

If the Doctor desires to exercise his undoubted privilege to change his opinion for one more generally held he should withdraw his former expression, not deny it.

Language is but an imperfect medium for the transmission of thought, as the courts teach us daily, but when Dr. Souchon, after relating what quarantine had done in preventing yellow fever in New Orleans, says: "All that was accomplished without any precautions whatever having been taken against mosquitos," he implies that quarantine, in his opinion, need not consider the mosquito.

It is quite possible that the Doctor regrets having expressed this erroneous belief, but that, as Kipling would put it, is "another story."

In the very first paragraph of the Doctor's reply he furnishes the keynote to his argument, whose dominant tone harmonizes neither with science nor ethics—the one requiring accuracy, the other demanding fairness. In the first sentence of this paragraph the Doctor betrays a misinterpretation of the quotation with which I caption my article. In the second sentence he announces his idea of progress to be "to strive to make knowledge," and in the third he forthwith carries this idea into execution by boldly asserting a belief in the correctness of his own figures which is comparatively valueless, because utterly unsupported.

The mere belief of no man is sufficient warrant to establish as true that which is not true; and when the correctness of the Doctor's figures is challenged by specific reference *by date and page* to the official records (*of which he is the official custodian*), he should reply—if he reply at all—by something more specific and of greater convincing power than the mere reassertion of his own individual belief. Knowledge is not "made" in this way.

The Doctor charges me with failing to reply to the "point" of his paper, which was directed, I presume, against the importance of mosquito destruction in Havana for the prevention of yellow fever.

It was not my design to defend Major Gorgas, who needs no help, but to meet Dr. Souchon when he turned the "point" of his paper to attack my views on quarantine (with regard to mosquitos) previously officially communicated to him.

Perhaps the point of the Doctor's paper was also directed to show the great efficiency of the Havana quarantine; if so, then I met this point when I said, "Fomites could have entered Havana through its quarantine, but mosquitos could not."

Dr. Souchon contends "that the stegomyia on board of non-infected fruit vessels from ports quarantined against yellow fever are an unimportant factor in the transmission of yellow fever, because these mosquitos are very few in number and because they are not infected." I quite agree with the Doctor on this point; I even go further, and am willing to say that a mosquito or a vessel that is not infected, be she few or multitudinous, is not only "unimportant" but is actually non-existent as a factor in the transmission of yellow fever. It may be suggested very respectfully, however, that we sometimes don't *know* when a mosquito or a vessel, or a port, or even a person is infected; and to assume an absolute knowledge we cannot possess is absurd.

The Doctor asserts that investigations show 2½ per cent. of stegomyia on fruit vessels, and that only one case of yellow fever was discovered on board of a fruit vessel which could not be traced to infection ashore. "If," says Dr. Souchon, "the mosquitos on board were infected there surely would have been more than one case in fifteen years on more than one thousand fruit vessels that came from the fruit ports during these years." The Doctor forgets to add that the crews of these vessels were selected by order of the quarantine authorities from acclimated sailors, and that the carrying of passengers was discouraged during the quarantine season; and further, that during the greater part of this period sulphur disinfection of the empty holds of fruiters was practised, and that this preventive measure was *not* in operation during the three years of yellow fever in New Orleans (1897, 1898, and 1899).

The Doctor is as unfortunate in his quotations as he is inaccurate in his statistics, for, after stating that "Reed and Carroll *do not believe* that infected mosquitos reach vessels," he proceeds immediately to quote Reed and Carroll (Medical Record, October 26, 1901), who say: "In our opinion the chances of infection of a vessel by contaminated mosquitos coming aboard from a house or ship in close proximity are *very slight*." I submit that the difference between "*do not believe*" and "*very slight*" is quite considerable; especially when such an important possibility is under consideration.

The Doctor refers to the investigations of Dr. Grubbs of the Gulf Quarantine Station, and selects that which serves his purpose best, as is his privilege.

Dr. Grubbs, in his report to the United States Public Health and Marine Hospital Service, comprising Bulletin No. 11 of the Yellow Fever Institute, states very clearly and plainly that three vessels out of eighty-two brought mosquitos of the stegomyia variety to the Gulf Quarantine, and no mention is made that all mosquitos on any vessel were ship bred. Dr. Grubbs closes his report with his conclusions, from which I quote:

I think we may conclude, first, that mosquitos can come aboard vessels under favorable conditions when the vessel is not over fifteen miles from shore; second, that *stegomyia* can be carried from Mexican or West Indian ports to those of our Gulf States; third, that they can board a vessel lying at anchor a half mile or less from shore, being conveyed by the open lighters used or flying aboard, and finally, that a vessel moored a short distance from land *may become infected with yellow fever, our old beliefs to the contrary notwithstanding.*

The gravamen of my offence seems to be my insistence

that commercial expediency should not prevent the disinfection of *all* fruit vessels, as was done during our long period of exemption from yellow fever, and as was *not* done during 1897, 1898, and 1899.

Quitman Kohnke, M.D.,

Health Officer of the City of New Orleans.

New Orleans, April 24, 1903.

SECONDARY ERUPTION IN MEASLES.

To the Editor of the Medical Record:

Sir: On page 751, issue of May 9, is an abstract entitled "A Rare Case of Measles," in which it is stated that an eruption appeared over the entire body fourteen days after the initial eruption of measles. If such cases are indeed rare, I would mention that in a recent epidemic in this locality, one of my patients, a man about thirty years of age, had the initial eruption of measles April 12, which ran the usual course, and April 29 he came to my office with a macular eruption all over the body and limbs, more nearly resembling scarlet fever than measles, which lasted about three days. Temperature taken once was 99.5°; constitutional disturbance slight. He thought eating strawberries may have been the cause, but had previously passed through no similar experience.

R. C. Shultz, M.D.

Los Angeles, Cal.

OUR BEYROUT LETTER.

(From Our Special Correspondent.

THE VARIABLE CLIMATE OF BEYROUT—CHOLERA AND THE QUARANTINE—INSANITARY CONDITIONS.

Beyrout, Syria, April 28, 1903.

Beyrout, after an unexampled display of cold and wet, has again betaken itself to its accustome season of sunlight and clear skies. There are tokens of spring, and the heat of summer is in the air.

The "oldest inhabitant" tells us that for eighty years past we have not had such a "winter"—bleak and cold, and with a rainfall 30 per cent above the average. A "bit wet," remarked one of some Scotch wanderers, going about in a summer suit in what might be veritably called a Syrian blizzard of rain, hail, and thunder last December. "Nae sae bad," said one of his compatriots "ay, an' it might hae been worse!" suggested the patriarch of the party. From these premises we may conclude that Beyrout, the "Pearl" of the East, has descended from her high estate and has become wintry after all.

This is April, and a month hence we may go through all the cold and hot vicissitudes of the seasons in one summer's day—a day of twenty-four hours. Summer, blazing hot in the morning, mellow autumn among the shadows of the hills in the evening; spring as we mount higher before the dawn comes, and higher and higher still we find ourselves among the snows of Lebanon the morning after, looking down upon our starting place wrapt in the hot haze of one of our yesterdays. And this we can do, and, oh, the bother of it, because a railway has been laid and transit is quick. The railway brings up another subject—quarantine, to wit; and with quarantine Beyrout has been pregnant for the last decade to our personal knowledge. When she is going to be delivered of her burden it is impossible for lookers-on to say, but when she is herself again we hope she will reconsider her position.

Some eighteen months ago she tried to produce plague; and it was an abortion—now she has been whispering to her sister—the ancient city of Damascus—that she might give us, in default, *her* charge of cholera. But we will have none of it. We can only sit down and listen to her dirge. Cholera had her surfeit in Egypt, wandered up to the borderland of Syria, took some spoil in Tiberias, one of the districts of dwelling places, skirmished in Jerusalem, and so went to her own place.

Dwellers in Damascus during what may be called "lucent intervals" of quarantine have visited us from time to time during the last six or seven months, and seem to take it as a personal matter when we doubt the genuineness of this sample of cholera. We can only say we have had no statistics of deaths, either officially or by report, which would even tempt us from our standpoint of incredulity. We wake up one morning to find the train was not running from here to Damascus. Then we heard that a quarantine had been established midway on the line and forty miles from here. From that day to this, land quarantine has been put on and taken off, varying in its intensity from fifteen days to twenty four hours. Its permutations and combinations would puzzle a mathematician, and its spasmodic energy and unknown *rationale* are comparable in their result on the residents here to what may be experienced by an unfortunate traveller on board a ship whose berth may be situated below or in immediate proximity to the donkey-engine.

The railway quarantine station is placed at the village of Moalaka-Zahley, a village of about 30,000 inhabitants, situated on the Beyrout-Damascus railway and about half way from either terminus. The Zahley portion of the village, containing perhaps three-fourths of the population, is Christian and under the Government of the Lebanon, and therefore under the protection of the European powers, the other, or Moalaka portion, is composed of Moslems, and in the village of Damascus, and therefore, like Beyrout, under the immediate rule of the Sultan. A *cordon* has been imposed between these two portions of the same village, and although the Moalaka inhabitants have free communication with the fertile neighboring plains whence the villagers are wont to obtain their food supply, those of the Zahley portion are not allowed communication with the adjoining villages nor with their Moalaka neighbors, and having their supplies thus cut off, are practically in a state of siege. They can, of course, get supplies by rail from Beyrout, but the expenses of transport, etc., would render the prices prohibitive. In sheer desperation the Zahley inhabitants about a week ago tried to break through the *cordon* in order to get food, and were, of course, fired on by the soldiers on guard, with the result that there were some thirty casualties. Dan. O'Connell, the famous Irish advocate, is reported to have said that he could drive a carriage and pair through any Act of Parliament that ever was framed, and we imagine that, even when not driven to extremities by the fear of starvation like the Zahley folk, people will, as they have always done, find ways and means of evading land quarantine in a way quite in keeping with O'Connell's law-breaking chariot.

An edict has gone forth that our streets shall be paved, and operations have commenced in that direction. Already bands of Italian workmen are busy on the "Place de Canons," the principal, or rather the only, square in the town, and it is hoped that the good work may be perfected and not, as is usual here, come to an untimely end. During the last season's rains, we have been surfeited with mud and our streets were more or less like unto quagmires, with here and there an open drain to lend variety. For this and for other causes we had to be careful of his outgoings and his incomings, especially after sunset. There was a state of lawlessness, be it said, abroad; strangers and European inhabitants were attacked and robbed in early morning and after dusk, and murderous attacks, in several instances with fatal results, were committed on some of the natives, both rich and poor, and in most cases without apparent reason. Matters seem to be adjusting themselves, and it is some three weeks since we heard of any stabbing or shooting cases—a fairly long interval, comparatively speaking, as things have been going on.

There have been no epidemics since the endemic dengue wore itself out about a year ago. Sporadic cases of typhoid fever and smallpox are always cropping up, and, thanks to the alternations of coagulated mud and dust, tuberculosis in every form is ever to the fore. Perhaps after the streets are paved there may be some tendency in the latter to seek other quarters—that is, if, after thus paving, the town authorities be of a mind to keep their paved streets clean.

Congenital Alopecia.—There are several very different opinions as to the cause of this condition of hair loss. Great prominence is given by the author to the two fundamental processes that precede the final development of the hair, the formation and growth of the lanugo hairs at the sixteenth week of fetal life and the subsequent falling of the lanugo hair and replacement thereof by long medullated hairs in the positions that they occupy in life. This change begins in the scalp at the end of the eighth month. Concluding that the condition of alopecia is due to interference with any of these rudimentary processes, the author sums up in the following two premises: (1) If there is any interference with the development of the process of lanugo formation, there will result a delay in final hair-growth, if not a complete cessation. (2) If the hair rudiments have formed, but are subjected to a later interference, there will result a delayed development of the hair, or the hairs may be of a weak type which show a tendency to atrophic changes, or there may be a nævus formation.—Prof. Bettmann, *Archiv für Dermatologie und Syphilis.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, May 28, 1903.

The Relation of Chronic Enlargement of the Spleen to Anæmia in Infancy.—John Lovett Morse concludes from his studies with complete examinations of the blood, in the case of twenty-two infants, that when anæmia, splenic tumor and enlargement of the liver or lymph nodes are found in association with infancy, they are in no way dependent on each other, but are all manifestations of a common cause—disturbance of nutrition; that there is nothing characteristic about the blood changes found in association with enlargement of the spleen, as similar changes are found when there is no enlargement of the spleen; that the anæmia is secondary rather than primary; that there is no justification for placing the cases of anæmia in infancy associated with enlargement of the spleen or liver in a class by themselves and calling it "anæmia infantum pseudoleukæmica," or "splenic anæmia in infancy," that these terms should be dropped from our nomenclature.

The Boston Medical and Surgical Journal, June 4, 1903.

The Surgery of the Simple Diseases of the Stomach.—B. G. A. Moynihan in the perforation of gastric or duodenal ulcers prefers a prompt operation to expectant treatment, and emphasizes the necessity of a thorough exploration of the stomach for other ulcers. In the case of hemorrhage from acute ulcer, medical measures will usually suffice; if not, gastroenterostomy is the operation to be preferred. In hemorrhage from chronic ulcer this same operation is to be performed. Chronic ulcers often occur in a masked or latent form, the diagnosis from dispepsia being difficult to make. In "hour-glass stomach" there is apt to be a dual stenosis, so that one operation will not suffice, but two operations will have to be performed at the same time.

Cardiospasm and Its Treatment.—Joh. von Mikulicz-Radecki has observed about twenty cases of this disease, which he describes as an affection of the œsophagus, which consists mainly of a sacculated or fusiform dilatation of the organ, most pronounced in its lowest portion. He describes an operation for the relief of this condition, which proved a complete success. The stomach was exposed by laporotomy, and an incision was made into the anterior wall wide enough to allow the entire left hand to pass into the stomach. Under guidance of the fingers, an instrument resembling a glove stretcher was pushed into the cardiac orifice, and dilatation was gradually effected to such an extent that the blades of the instrument were about 7 cm. apart. Thus was caused a blunt dilatation of the cardia similar to the dilatation of the sphincter ani in case of anal fissure. The wounds in the stomach and in the parietal walls were then closed.

Journal of the American Medical Association, June 6, 1903.

The Uses and Abuses of Venesection in the Practice of Medicine.—Robert Reyburn declares that in certain diseases venesection is a valuable therapeutic measure, and in some instances is absolutely necessary to save life. The class of maladies benefited by the abstraction of blood are those in which there is in the body an abnormal blood-pressure threatening the rupture of a vessel in the brain or a stasis of blood in some vital organ. Typical instances are cerebral engorgement, croupous pneumonia, and puerperal eclampsia. Attention is called to the increasing death rate in pneumonia. In this disease venesection takes away the surplus blood which is overfilling and engorging the blood vessels of the lung, and also diminishes the force and frequency of the heart, which is sending to the lung far more venous blood than it can purify. Reyburn believes that many cases of threatened puerperal eclampsia can be prevented by timely bleeding. He insists, however, that the field of application of venesection is very definitely limited to the province suggested by the statements in his paper.

A Diagnostic Examination of One Hundred and Fifty Cases of Leprosy.—J. T. McDonald presents the following conclusions: (1) The microscope is the supreme agent of the final diagnosis of leprosy. No patient should be committed to a segregated colony without a bacteriologic demonstration of the disease. (2) Of clinical symptoms, maculæ, chiefly leucodermic spots, are found in 89 per cent. of all cases. (3) The lepra nodule, found in 74 per cent., is the one chief distinguishing lesion of skin leprosy. (4) Thinning, or complete loss of eyebrows and lashes, is present in 63 per cent. (5) Atrophic changes in hands and forearms, with retraction and contraction of fingers and enlarged ulnar nerve, in 32 per cent., a leading feature of nerve leprosy. (6) The plantar ulcer, found in 26 per cent., usually on the ball of the foot. (7) Absorption of phalanges in 16 per cent., with occasional spontaneous amputation. (8) Elephantiasis of hands and feet in 16 per cent. (9) Facial paralysis in 11 per cent. (10) The entire body should be carefully tested for anæsthetic areas. (11) Several of the above symptoms can be found in some slight degree at least in every leprous subject.

Results in Radiotherapy.—H. R. Varney details his experience with radiotherapy in tuberculous lesions of the glands and joints, in various skin diseases, lupus and malignant tumors. In reporting his series of the latter, numbering 50 cases, he states that it is only fair to the treatment to state that out of this number 38 were absolutely grave, inoperable, recurrent cases, so conceded by reputable surgeons, 13 were sarcoma, 6 lymphosarcoma, and 7 osteosarcoma; 37 carcinoma, 19 of which were epithelioma. The results of these cases can be summed up, briefly, as follows: With the exception of 8 cases, which are still under treatment, one year has elapsed since the rest were discharged, those living to date being constantly under observation or in communication. Cases ending fatally, 10; discharged improved, treatment discontinued, 5; referred for operation, 4; improved and still under treatment, 8; referred to other operators, 4; discharged, clinically cured, 19. The ages of the patients ranged from 18 to 84—19 females, 31 males. In cases of breast cancer the author finds a relief from pain, and sometimes a diminution in size of the new growth and its final disappearance, so that the case is clinically cured. He finds that malignant growths of the breast pathologically the same do not react the same to the rays. This depends on the resistance of the normal cell structure. Operation combined with radiotherapy offers encouraging ground for work. In treating epithelioma Varney believes it is necessary to give the longest exposures that can safely be given, to gain the promptest and best results, for it seems possible, with mild treatment, to stimulate growth, and, if long continued, to cause the disease.

Medical News, June 6, 1903.

A Case of Bacteriuria Resembling Weil's Disease.—G. Reese Satterlee presents the following summary of this paper: The picture presented by the original case was that of an acute febrile jaundice. There was a severe general infection, which must have caused degenerative changes in the liver as well as in the kidney cells. The prolonged weakness and the general muscular pains during convalescence showed that the infection was a severe general one. Experiments with a bacillus isolated from the urine, showed it to be toxic to guinea-pigs and in a lesser degree to rabbits. Acute hepatitis was marked in all cases that came to autopsy. Acute nephritis was also found. In the animal which survived the inoculation, the urine showed bacteriuria with albumin and casts.

New York Medical Journal, June 6, 1903.

Aids to Cystoscopic Practice.—F. C. Valentine has devised an apparatus which he calls a "box-phantom," looking into which through a cystoscope, the observer sees appearances such as those presented by the bladder in health and disease. In addition to this there is a larger phantom for advanced study. These are both figured in the original paper, which also contains directions for their use. Valentine believes that with these pieces of apparatus students may be easily and intelligently taught the methods of cystoscopy.

Torsion of the Testicle.—The symptoms, diagnosis, and general treatment of this rare condition are discussed by W. W. Williams, who adds notes of a personal case. His patient was a young man, aged sixteen years, who suffered from a sudden and intense pain in the right groin and testis. A hernia was found and reduced, giving some relief, but the epididymis was found to be enlarged and turned toward the front. This was replaced and immediate relief ensued. A second attack followed in a few days, and a similar condition of the epididymis was found. Replacement was tried but could not be performed. Consequently an incision was made over the cord and testis, and two drachms of bloody serous fluid escaped from around the cord. The testicle and lower portion of cord were black in color, due to a torsion of the testicle causing strangulation. The cord was ligated high up with fine silk and divided below the ligature. The author had placed an artery forceps on the cord above the testicle before dividing the cord and removing the testicle. When the forceps was removed, about one ounce of black blood escaped from the testicle and cord. The wound was closed with fine silk stitches, and a sterile dressing applied, held in place with a crossed perineal bandage. The stitches were removed the seventh day, and the patient went home on the thirteenth day. He has not had any pain since the operation.

Blepharitis Marginalis.—Three classes of cases are described by D. S. Reynolds. In the first class, the anterior

margins of the lids are dry and red, and the lash is seen, on close observation, to be thin, while the cuticle between the hairs is covered with minute scales of desquamating epidermis. There is slight thickening along the borders of the lids. In the second class, there is an excoriated, red, glazed, rounded appearance of the tarsal margin with no sign of lash. Rarely are both eyes affected in equal degree. In the third class there is an abundant accumulation of inspissated serum matting the lashes together in groups. When the crust is removed most of the hairs come away with it. There may be great thickening of the lid margins, and over its under surface dilated veins may course. In the first case the fungus surrounding the hair follicles may be destroyed by applications of a needle dipped in pure carbolic acid. The same remedy is also of service in the second class, in which the author believes ointments of all kinds practically useless. Thorough cleansing in the third class should be followed also with phenol applied to the bottom of the ulcer left by the detachment of the crust. The patient may now have a piece of gauze, smeared with petrolatum, laid over the closed lids, and a bit of cotton wool on the outside of the gauze, secured with a few strips of plaster, laid from the cheek to the forehead. This dressing should not be disturbed for twenty-four hours, when the treatment may be repeated, if necessary. Careful search should be made for any constitutional abnormality, which if found must be carefully corrected.

American Medicine, June 6, 1903.

Isolysins in the Serum of Disease.—S. Peskind has recently observed the presence in the serum of a leukæmic patient of an isolysin, *i.e.* a substance which caused hæmolysis of human blood-corpuscles. This hæmolysin may have been a product of the disease, or it may have been derived from the leucocytes, which were present in enormous numbers. The writer then experimented with the sera in other diseases to determine if isolysins were present, and if so, whether such isolysins were specific for these diseases or not. In a case of leukæmia, laking was almost complete in a short time. In two cases of anæmia there was no hæmolysis after some hours. In a case of pneumonia there was no hæmolysis after forty-eight hours. In a case of cancer of the stomach, laking was not complete at the end of forty-eight hours. In a case of cancer of the breast of one year's standing, agglutination took place in all the tubes. There was no hæmolysis after four days. The sera from two cases of typhoid fever and a case of uræmia, caused absolutely no laking of normal human blood-corpuscles after two or three days, even though drying out had occurred at the ends of the tube. But the sera in all these cases produced rapid laking of each other's blood-corpuscles, the laking beginning at the ends of the tubes where slight drying out had occurred. This laking in all probability is due to the lowered resistance of the blood-corpuscles in these diseases to hyperisotonic solutions. It is conceivable that these investigations may be of use in diagnosis.

The Medicolegal Test of Blood-stains.—E. N. Layton concludes that: (1) The reaction is caused by the development within the blood-serum of the injected animal of an anti-body or a property or substance which causes a certain reaction with the serum homologous to the one injected. (2) The reaction does not occur when normal rabbit serum is used. (3) The reaction occurs much more rapidly, especially when dilute solutions are used, if the test is exposed to a temperature of 37°C., although it will occur at ordinary room temperature. (4) An immediate result in the cold is obtainable by diluting only the blood tested, the test serum being used pure. (5) The reaction is obtainable when using a dilution of the test serum of 1-20,000, or of the blood tested of 1-4,000. Hence, only a minute stain and a single drop of the test-serum are required for making the test. (6) The delicacy of the test is not altered by the admixture of other bloods or of other foreign material, except the albumin precipitants. (7) The presence or absence of mineral salts, such as copper sulfate, or of other precipitants of albumin, can be determined by the control tests. (8) The delicacy of the test is not materially altered by the age of the stain. (9) A differentiation from monkey blood is possible, and contamination with monkey blood can be excluded, first, by a great dilution of the blood tested and a dilution of the test-serum of 1-500, with incubation; second, by a great dilution of the blood tested, the test-serum being used pure, and the test made at room temperature. (10) The test is specific, invariable, and therefore applicable to forensic use.

Philadelphia Medical Journal, June 6, 1903.

Wounds Inflicted by Modern Agricultural Implements.—D. W. Basham declares that to treat these wounds successfully, it is necessary for the surgeon to be skilled in the operation of tendon suture and nerve suture. Of all wounds to which farmers are most liable, none is so serious as those inflicted by the threshing-machine and the cotton-gin. In both cases amputation is generally required. One should never despair of a member so long as the blood supply is adequate to the needs of the parts and the promotion of the healing process. After correct antisepsis and asepsis, these wounds may be closed up, even though a joint be involved, the same as we close the abdomen under similar conditions, and the same results may be anticipated in the one case as in the other.

The Treatment of Otitis Media Suppurativa Acuta.—S. Maccuen Smith says that in the treatment of this affection it must be assumed that every effort has been made to arrest the disease before the formation of pus. But if this has already formed, it should be evacuated by a free incision of the membrana tympani, but never by simple puncture. After evacuation of the fluid from the tympanic cavity, a good recovery will be made in many cases by cleansing the canal and middle ear with an antiseptic solution followed by introducing a strip of iodoform gauze well into the deep canal to provide for good drainage, to be renewed every day or two. After the secretions have been removed by inflation, irrigation, or a cotton carrier, the surface can be gently dried with cotton and hot air, and then dusted with some impalpable powder. The general health must not be neglected. Absolute rest in bed, with free diuresis and properly conducted diaphoresis, are of the first importance. The bowels should be freely opened and the diet restricted to milk and broth. One or two days of absolute fasting and enforced rest in bed will often do more in prophylaxis than any other single or combined therapeutic measures.

The Lancet, May 30, 1903.

The Therapeutic Value of Alternating Currents Applied to the Abdominal Sympathetic Nervous System.—S. Sloan concludes as follows: (1) Those cases of uncomplicated neuromuscular asthenia in which the cause had ceased or had been removed most amenable to the treatment. By neuromuscular asthenia he means neurasthenia minus its psychic elements. (2) Regarding cases of visceral neuroses almost as much can be said. (3) Cases of persistent sickness, some of them of reflex character, have done well under the treatment, the only failure in this list having been one in which the liver was considerably enlarged. (4) The treatment may be relied upon in vasomotor cases, all of the five cases having been successful. (5) The treatment will be of little avail in neurasthenia. (6) In cases in which inflammatory mischief existed in the pelvic organs the result is not likely to be good. In such cases vaginal electric applications have given the best results. (7) When septic endometritis exists only a very temporary improvement will follow, although this may be made a permanent one if the treatment is resorted to after curettage has removed the septic condition from the uterus. (8) Epileptics are likely to derive no benefit from the treatment.

Uncomplicated Myocarditis in Children.—The histories of four cases are given by G. Carpenter. In case 1 there was a strong family history of phthisis, and certain preceding symptoms strongly suggestive of diphtheria. In case 2 the cause was undetermined, while in case 3 the cause was undoubtedly rheumatism. Pure myocarditis is rare in children. Of fifty-six cases of the chronic form Quain found but three in children. The commonly recognized causation of the acute disorder is pyæmia from bone and joint troubles. The common sequence in the acute form is abscess formation in the heart wall. This either bursts into the pericardial sac, forming a purulent pericarditis, or into the endocardium, and sets up an acute cardiac aneurysm. In all these cases, which are free from endocarditis, there are systolic and presystolic murmurs. It would appear, says the author, that the mitral murmur requires merely for its production a leaky valve, that no roughness or irregularity of the segments is necessary to that end, and that a mitral murmur is not positively diagnostic of mitral endocarditis, though it is, of mitral insufficiency. He also believes that the presystolic and mitral diastolic murmurs are indicative of a disturbance of the normal relationship between the size of the mitral orfice and the left auricle. When the latter is distended and the mitral ring distorted, this normal relationship is altered so that we have a *comparative* narrowing of the mitral orifice that is a mitral stenosis for that particular heart, and that murmurs which depend upon these anatomical changes are indistinguishable clinically from the systolic and presytolic and diastolic murmurs of ordinary mitral disease and true mitral stenosis, and that when these murmurs are present they are certainly much more in favor of endocarditis than the reverse by reason of the greater comparative frequency of

that condition in heart disease, with the reservation that mitral stenosis in childhood is a rarity.

The Differentiation of the Continued and Remittent Fevers of the Tropics by the Blood Changes.—L. Rogers gives this subject an exhaustive discussion, illustrating his statements by a series of statistical tables and charts. The various fevers considered are typhoid in Europeans and native Indians, malarial remittent, simple continued, non-malarial remittent, low, and malta. Twelve clinical histories are summarized. A marked increase in the percentage of lymphocytes without any noteworthy increase of the large mononuclear white corpuscles is of value in differentiating typhoid from malarial remittent fever. This test is, of course, in addition to that of serum injections, and the determination of malarial organisms. In malarial remittent there is a larger mononuclear increase. From the author's extensive experience, he concludes that only two forms exist at any rate of long duration—namely, typhoid and malarial remittent. Furthermore these can be distinguished in a considerable proportion of the cases by purely clinical methods, of which the temperature curve and pulse-rate and presence or absence of abdominal symptoms and the action of quinine are the most important. The remainder can be differentiated by the serum test or by the differential leucocyte count in all but a very few exceptional cases, the leucocyte count being of special value in the tropics on account of its being available when parasites are absent as a result of previous quinine treatment and its not requiring a laboratory—laboratories being very few and far between in the tropics at the present time—while it also has some prognostic value. "Simple continued fever," if it exists at all as a separate entity, which still remains to be proved, is very rare indeed as compared with malarial fevers. The so-called "non-malarial remittent fever in natives has been shown by the serum test to be nothing but typhoid fever. Low fever is distinct clinically, but is probably the result of the debilitating influences of prolonged residence in a tropical climate, including latent malaria, and is not a new specific fever.

British Medical Journal, May 30, 1903.

Case of Appendicitis in a Woman Aged Seventy-eight Years; Operation; Recovery.—A. R. Walters observed this patient. She had suffered from constipation for many years. She was of rheumatic habit. When seen on this occasion, she was suffering from abdominal pain and constipation. The temperature rose, vomiting occurred, swelling in the right iliac fossa and general tympanites, with great pain, developed. Appendicitis was diagnosed, and operation was performed. In spite of her great age, the patient made an excellent recovery.

Guaiacol in the Treatment of Smallpox.—J. J. Ridge states that in his experience in the treatment of smallpox, aside from four unvaccinated young infants who died—almost hopeless cases—there was but one death in forty-four cases. That case was one of confluent smallpox in a man aged forty-seven years, of intemperate habits and not vaccinated since infancy. The favorable courses of these cases reported is attributed chiefly to the use of guaiacal dissolved in olive oil—1 part to 80. The whole surface was annointed with this with a cotton swab at least every four hours. It allayed the irritation, and after a few applications almost abolished it. The medicine given was a hydrochloric acid mixture. The diet was simple milk and broth till convalescence. No alcohol was given. The loathsome odor was almost entirely abolished.

Clinical Observations on the Treatment of Inoperable Cancer by Formalin.—A. F. Meredith Powell reports his observations on this subject. In from three to seven days after application the cancer mass begins to detach itself in the way that necrosed tissue separates in gangrene. A line of demarcation is formed at the edge of the malignant mass. From twenty-four to forty-eight hours after the first application, the foul-smelling discharges cease. The patient becomes more bright and cheerful. In from twelve to sixteen days the writer was able to remove the growths in three cases—a sarcoma of the breast, a scirrhus of the breast, and an epithelioma of the lip (recurrent), leaving in its stead healthy granulating tissue, the skin gradually growing and closing the wound up. The process of separating is completed by the aid of a pair of forceps and scissors to snip the fibrous bands that pass into the underlying granulations. The strength of the formalin solution should be between 1½ and 2 per cent. Absorbent lint soaked in 2 per cent. formalin solution is laid on the tumor. This is covered with jaconet and cotton wool and bandaged on. The dressing should be changed six-hourly. After the third or fourth dressing the discharges and fetor cease. The further process is an aseptic one.

Case of Trypanosomiasis.—Patrick Manson reports this case observed in a woman of forty years. The temperature, as a rule, ranged from about 97° F. in the morning, to 100° F. in the evening. The pulse was always rapid and feeble. The erythema, which was a remarkable feature in the case, was first observed during the primary fever when the patient was living on the Congo. At that time she suffered much from prickly heat. The œdema, like the erythema, was most pronounced on the back and face. There was marked enlargement of the spleen. The red corpuscles were diminished in number, but, except for a short time during treatment with horse serum, not to any very great extent. The highest count was 3,880,000. The hæmoglobin was reduced in about the same proportion as the red corpuscles—36 per cent. was the lowest estimate. The red corpuscles were fairly uniform in size; there was no poikilocytosis. Only four nucleated reds were found altogether. The leucocytes were slightly below the normal number in most counts. There was an excess of the mononuclear elements. The polynuclears and eosinophiles were fewer than normal. The patient was kept in bed in a warm room and fed well. Arsenic in the form of sodium cacodylate or arsenate of iron was given hypodermically. Methylene blue was given. Horse serum was injected, but this treatment had to be stopped on account of the developing of serious symptoms.

Deutsche medicinische Wochenschrift, May 14, 1903.

Relations of Mild Infections to the Blood-forming Organs.—Felix Fregmuth, as the result of experimental research, shows that very small doses of infective agents which give rise to scarcely any clinical symptoms exert a specific action upon the blood-forming organs and excite in them an increased activity, which they do not possess under normal conditions. Hence slight infections which pass without clinical notice may subsequently give rise to severe derangements of the blood-forming organs, such as severe anæmia, chlorosis, etc. The experiments were carried on with cultures of typhoid bacilli or their toxins, which were inoculated in minute doses into rabbits. The hæmatological changes were studied by subsequently killing the animals and examining the bone marrow.

Pulsus Paradoxus.—Franz Riegel thinks that this condition, which was originally described by Griesinger in 1856, may etiologically be divided into three classes: In the first group of patients the symptom is due to a mediastinal pericarditis and caused by a direct mechanical compression of the great vessels. In the second class the origin is to be sought in a laryngeal or tracheal stenosis. Here the diminished admission of air into the lungs marked increases the normal variations in blood-pressure seen in normal respiration and produces the pulsus paradoxus. To the third class belong cases of various pulmonary and pleural diseases. In both of the latter classes pulsus paradoxus does not develop so long as the power of the heart remains good, and its presence in them is an absolute sign of diminished cardiac activity.

Berliner klinische Wochenschrift, May 18, 1903.

Etiology of Tabes.—E. von Leyden considers the exciting causes of tabes without especially entering into the consideration as to whether or no a syphilitic basis is necessary for its development. Such causes are traumatism, over-exertion, and cold. Cases are cited which exemplify these varieties of direct causation, and the fact is brought out that in several of them no personal or hereditary syphilitic history could be obtained. Experimental observations has also shown that traumatism, at least, may be followed by a degeneration of the posterior columns, cornu, and nerve roots, which in a typical manner correspond to the lesions of tabes.

Temperature Relations of Chronically Diseased and Congested Joints.—Max Herz concludes that the temperature of chronically diseased joints is always lower than normal. The slighest venous congestion increases the temperature of the extremity and calls forth in addition to the passive also an active hyperæmia. The pronounced compression of a vein produces first an increase in temperature and then a decrease, while a decrease is always immediately produced by the compression of an artery. When congested, the temperature of an extremity is more increased in a "light" bath and more decreased by the application of cold water than when the circulation is free.

Munchener medicinische Wochenschrift, May 19, 1903.

Appendicitis and Intestinal Worms.—W. Oppe reviews the literature and reports his observations upon sixty cases of appendicitis. Of these, five showed the presence of intestinal worms in the appendix. In all the cases the

oxyuris vermicularis was the sole parasite found. The number present varied from 2 to 8. There can be no doubt but that these parasites are a more frequent cause of appendicitis than is generally supposed.

A Case of Pleuritis Pulsans Dextra.—Ernst Bendix reports a rare case of pulsating pleurisy. The patient had suffered from acute articular rheumatism just previous to the development of the pleurisy. When first examined the physical signs of pleurisy with effusion were well marked, and the pulsations which corresponded in time with the cardiac impulse were painly evident. Evacuation of the pleural exudate was promptly followed by a permanent disappearance of the pulsations. From a diagnostic standpoint aneurysm is regarded by most authors as very liable to be confounded with pulsating pleurisy. Careful percussion and auscultation, however, never fail to give a plain differentiation between these conditions.

French and Italian Journals.

Tuberculous Osteoperiostitis of the Alveolar Border.—Ginestous and Lavie had a patient, a little girl of twelve years, who was afflicted with tuberculous osteoperiostitis of the alveolar border. In 1900 she had a blow over the left eye, and some time after, she noticed a hard tumor developing at the level of the superior orbital border. It was as large as an almond. It formed an abscess, and in spite of careful treatment, continued to suppurate. Other bony abscesses developed in like manner at other points.—*Gazette Hebdomadaire des Sciences Médicales*, May 17, 1903.

Abscess of the Spleen.—Angelo Cipollina reports a case of this rare disease. Among the most important symptoms he calls attention to the fever which may be continuous, or remittant, but is usually typically pyæmic. The general symptoms consist of the typhoid state, loss of strength, and a small and rapid pulse. As to the local signs, the spleen may be only slightly or very much enlarged. Pain is present, due to irritation of the capsule; to relieve it the patient usually assumes the position of dorsal decubitus with flexion of the left thigh. Prognosis of this affection is grave, surgical treatment the only resource.—*La Riforma Medica*, May 13, 1903.

Intervention in Pulmonary Gangrene.—Lejars discusses this question. He has operated five times in these cases. The results vary widely. In one of his cases, he resected two ribs and opened the pleura. After reaching the cavity, there poured out a pulpy material, black, thick, and horribly fetid. Ample drainage was made, and perfect cure resulted without even a trace of adhesions. But a second patient who presented equally all the signs of pulmonary gangrene, and who received the same treatment, although he recovered well from his operation, still coughs and expectorates. The writer thought that it was better to leave the treatment of pulmonary gangrene to the physicians, unless there were clear signs of a very localized focus, and of cavity formation. Besides, the other lung ought to be in good condition. Thoracotomy should be ample, and several ribs should be removed.—*Gazette des Hôpitaux Civils et Militaires*, May 16, 1903.

Sudden Death in the Course of, or After the Operation for Appendicitis.—Jalaguier reports three cases observed one after the other in the course of fifteen days, of pulmonary embolism coming on shortly after the operation for appendicitis. In two cases the operation was limited to the opening of purulent peri-appendicular or sub-hepatic foci. The patients at first did well, relatively speaking, then suddenly, after some days, embolism occurred. One of the patients died, the other recovered. The third case concerned an operation between attacks. The patient was doing well and the sequelæ were most favorable. But embolism developed on the twelfth day. This patient also recovered. Jalaguier declared that this was the first time that he had observed pulmonary embolism after operations for appendicitis.—*La Presse Médicale*, May 23, 1903.

Annals of Surgery, April, 1903.

Primary Carcinoma of the Vermiform Appendix with a Report of Three Cases.—From a study of the subject, and the results of personal experience, A. W. Elting reaches the following conclusions: (1) Primary carcinoma of the appendix is not of such rare occurrence as has been hitherto supposed. (2) Every appendix removed at operation or autopsy, if it presents any evidence whatever of disease, should be examined most carefully, and sections should be made from several portions of the organ for microscopical study. (3) The relationship of primary carcinoma of the appendix to chronic appendicitis, especially of the obliterative type, seems to be fairly definitely established. (4) Primary carcinoma of the appendix shows a tendency to develop at a comparatively early period of life. (5) Primary carcinoma of the appendix does not show a marked tendency either to extension or to metastasis. (6) The symptoms of primary carcinoma of the appendix are usually the symptoms of appendicitis of the chronic type. (7) The diagnosis of primary carcinoma of the appendix is in the great majority of cases impossible. (8) The treatment of the condition should always be operative.

Bulletin of the Johns Hopkins Hospital, May, 1903.

On the Occurrence of Diastolic Murmurs without Lesions of the Aortic or Pulmonary Valves.—Richard C. Cabot and Edwin A. Locke give the following summary and conclusions: (1) Diastolic murmurs without organic valve lesions are not uncommon in connection with dilatation of the aorta, localized or diffused. One of the writer's cases seems to be of this type. (2) When the pleura and pericardium are adherent, owing to tuberculosis or other causes, diastolic murmurs are occasionally audible in the præcordia. Such murmurs are notably affected by respiration and by position; they are probably due, in most cases, to suction or pulsion exerted by the heart upon portions of lung adherent to the pericardium ("cardio-respiratory murmurs"). (3) In cases of intense anæmia, when the red cells are reduced to or below 1,000,000 per cubic mm., one occasionally hears diastolic murmurs not to be explained by permanent dilatation of the aortic ring, nor as "cardio-respiratory murmurs," and not due to a diastolic accentuation of a venus hum. The cause of these murmurs is obscure.

Angioneurotic Erythema and Its Surgical Treatment by Neurectomy.—Joseph C. Bloodgood reports three cases. In the first case he remarks that the areas of erythema differ from the usual cases of angioneurotic œdema, in the persistence of the vasomotor dilatation. Associated with this persistent hyperæmia there is increased sensibility to touch, but decreased sensation to pain; sensation to heat and cold are apparently not disturbed. The areas on the cheek were far more painful and tender than those on the abdomen. In all of the areas the erythema could be made to disappear by continuous pressure; though the condition reappeared at once when pressure was discontinued. Neurectomy was performed with so far permanent relief. The œdema affected both cheeks, secondary to drainage of the antrum cavities for which neurectomy of the infra-orbital nerves was done. A second area on the left side of the abdomen was relieved by the division of the intercostal nerves. In the second case there was angioneurotic œdema of the mastoid. Chronic nephritis contraindicated ether anæsthesia. The third case was one of angioneurotic œdema of the elbow joint. At operation all of the tissues were normal except the periosteum. In separating this from the bone the outer table of the humerus was found a little rougher than usual. Upon chiselling into the external condyle, the bone was found to be normal. The œdema disappeared in a few days, but in a few weeks returned. Application of collodion greatly relieved the pain.

The Scottish Medical and Surgical Journal, May, 1903.

Notes of the Method of Eliciting the "Coin Percussion Sound" in Pneumothorax.—Hamilton Graham Langwill says that instead of making use of coins for the percussion element, let the chest wall be flicked by the finger and thumb while the physician auscultates. It will be found that the "flick" or "fillip" which is heard through the stethoscope over the normal chest as a dull thud, is at once converted into a ringing or chiming sound whenever the pneumothorax area is reached. The difference of sound heard over the unaffected and the affected area is so pronounced, that it is more easy to map out the extent of the affected area than by the old method, and also to detect a comparatively small pneumothorax. The procedure is much simpler than the other, and more rapid; no assistant is required, and if a binaural stethoscope is used the physician can see to map out with a pencil the limits defined by his percussion

The Edinburgh Medical Journal, May, 1903.

The Selection of Cases of Pulmonary Tuberculosis for Sanatorium Treatment.—T. N. Kelynack says that, concisely summarized, the most favorable cases for sanatorium treatment are full-grown, well-built adults, with normal development of chest, good breathers, without antecedent disease, of healthy stock, and trained in such occupation as does not necessarily expose to non-hygienic conditions. Among the unfavorable cases are, subjects below puberty and of advanced age. Low-class town dwellers, ill developed, with misshapen chest and deficient respiratory powers, of reckless habits or undisciplined mode of life, with bad family history, and giving evidence of previous lung enfeeblement, and general deficiency in vigor. Patients in whom tubercle has been implanted on an old chronic, bronchitic and emphysematous base generally prove unsatisfactory. When there is widespread cavitation, the benefit gained is usually but briefly retained. Phthisical patients, the subjects of serious organic affection usually gain no permanent benefit by residence at a sanatorium.

AMERICAN GYNECOLOGICAL SOCIETY.

(Continued from page 923)

EXECUTIVE SESSION.

Election of Officers.—*President*, Dr. E. Reynolds of Boston; *First Vice-President*, Dr. Whitridge Williams of Baltimore; *Second Vice-President*, Dr. E. P. Davis of Philadelphia; *Secretary*, Dr. J. Riddle Goffe of New York; *Treasurer*, Dr. J. Montgomery Baldy of Philadelphia; *New Member of Council*, Dr. Joseph E. Janvrin of New York.

The next meeting of the society will take place in Boston, on the fourth Tuesday in May, 1904.

THIRD DAY—THURSDAY, MAY 14.

Dr. Philander A. Harris of Paterson began the discussion of the two last papers of yesterday's session. He said he believed that it was hard to accomplish much in cases of carcinoma of the cervix uteri. He had one case in which the vagina was not involved, that was well after seven years; only a few cases lived more than three or four years; he had had only one case of carcinoma of the external genitalia. The patient was a woman of seventy years; she died less than two and a half years after operation.

Dr. Noble of Philadelphia said that there was a certain percentage of cures in carcinoma of the cervix, though the results in this field were not so good as elsewhere in the body. Treatment consisted of currettage, and the application of chloride of zinc. It might be thought that the cure was worse than the disease, for bad fistulæ often resulted. One patient had remained well for seventeen years; another for thirteen years. He had had four cases of carcinoma of the external genitals; one case of carcinoma of the clitoris was well after one and one-half years. He had removed entirely the external genitals as well as the inguinal glands.

Dr. J. Wesley Bovee of Washington said that he had seen no case of carcinoma of the vulva which would justify any treatment but cauterization. Few cases of carcinoma of the uterus were cured. In a case of carcinoma of the uterus the earlier the disease, the more radical the proceeding should be. He called attention to the electrothermic angiotribe of Downes; he said that it was excellent to use in carcinoma of the uterus.

Dr. I. S. Stone of Washington said that he had seen many cases called inoperable, which after cauterization, had lived three or four years. He thought that chloride of zinc should be used even before operation; the electric angiotribe—to some extent—filled the indications; it was easy to re-infect a raw surface in a case of carcinoma.

Dr. Matthew D. Mann of Buffalo said that it was curious that some apparently hopeless cases turned out so well. He had a case of carcinoma of the cervix some years ago in which he tried to do vaginal hysterectomy, but could not, because the organ was so fixed; he did high amputation and the patient was now well. These cases ought to give encouragement. Some hopeful cases turned out hopeless. He had not used the electric cautery much. He had seen three cases of carcinoma of the vulva; one was the worst case of carcinoma he ever saw. The disease extended down on the perineum. He scraped it and cut it away and exposed it to the *x*-rays. He also used antitoxin, but the case grew worse under that. The second case is now under his care; operation had been followed by primary union; in this case, also, he used the *x*-rays, and now, three months later, there had been no recurrence. He should keep up the *x*-rays, perhaps, for a year. He was surprised that no one had mentioned the *x*-ray in the treatment of carcinoma. In some cases it did much good; pain and hemorrhage and discharge stopped; other cases went on just the same, with no effect from the treatment. He thought this treatment should be tried extensively.

Dr. Cushing said that he had seen two cases of carcinoma of the vulva. He had operated upon both; both recurred. In carcinoma of the uterus some of his worst cases had recovered. Some of the apparently most hopeful had recurred. Not enough attention was paid to the infection of raw surfaces. He believed in removing the glands and fat; the same principle prevailed as in carcinoma of the breast.

Dr. Thaddeus A. Reamy of Cincinnati called attention to the specific character of this paper—Carcinoma of the Cervix. Carcinoma of the body of the uterus in a certain number of cases would be cured; the cervix seemed to be a favorable field for primary carcinoma. If it could be established beyond controversy that the case of carcinoma of the cervix was cured, it might shed some light upon the etiology of this trouble. If the removal of this carcinomatous tissue was followed by cure, then it would settle the fact that the disease was local. He could cite many cases in which there had been no recurrence after five or six years.

Dr. Reuben Peterson of Ann Arbor closed the discussion. He emphasized the point that the lymphatics were not always involved in carcinoma of the vulva. There were two distinct classes of cases of carcinoma of the cervix and vulva; perhaps this might explain the strange phenomenon about these cases—there might be a carcinoma only as large as a finger-nail, and extensive operation would be followed by recurrence; in other cases the growth might be greater, with no recurrence. We were dealing with two distinct kinds of carcinoma. The same held true in carcinoma of the breast. In case of carcinoma of the breast there might be a very small focus with infected glands; in other cases, there would be more extensive trouble of the breast, but no recurrence after operation.

Discussion: Should the Uterus Be Removed in Cases of Double Pyosalpinx, When Operating through Either the Abdomen or the Vagina?—Dr. Philander A. Harris of Paterson said that all women who had double pyosalpinx were sterile, and that most of them would remain so in spite of treatment or operation; that they suffer more or less from pelvic pains, not only in connection with movements of the body but independently of them. Pain varied with the case; increased temperature, headaches, constipation, and emaciation characterized a large proportion of cases. He had had one case which carried a temperature from one to two degrees above normal daily for one year and until operated upon; but neither fever, headache, nor emaciation was common to all cases. Menorrhagia with clots and a lengthening of the menstrual period was a common accompaniment of pus tubes. Such patients often said that they menstruated ahead of time. Dysmenorrhœa was present as a result of infection in about two-thirds of all cases. If menstruation was painful before the existence of pus tubes the painful period was more prolonged and the suffering far more pronounced. Leucorrhœa was generally very profuse in the beginning of uterine and tubal infection. It was nearly always present in a degree, but there were many cases in which it almost ceased or was not complained of and disappeared for weeks or months while the disease was progressing in the tubes and ovaries. As a consequence of double pyosalpinx, both sexual inclination and capacity for participation were greatly diminished. In isolated cases inclination for coitus was markedly increased. Far more often it was repressed, while the pain caused by the sexual act disinclined—if it did not forbid—participation. The above were the more important complaints and accompaniments of pyosalpinx. For the past four years the speaker's operations for diseased tubes had consisted principally of bilateral exsection of the tubes; consequently leaving both ovaries, one, or part of an ovary, and the maintenance of menstruation in at least 95 per cent. of all the cases operated upon. In the past four and a half

years he had performed about 150 abdominal sections in which both tubes were exsected in every instance; most of the patients were cured of all the pelvic pains and discomforts complained of after the occurrence of the tubal infection. Ninety-five per cent. continued to menstruate, while probably 90 per cent. returned to the menstrual habit, which characterizes menstruation prior to the infection. If menstruation had been painless prior to the uterine and tubal infection, simple excision of the diseased tubes cured the dysmenorrhœa, which arose from such infection; if the dysmenorrhœa was a regular part of menstruation prior to the uterine and tubal infection, excision of both pus tubes had little—if any—effect upon such primary dysmenorrhœa. The more grave and distressing and persistent symptoms referable to pelvic inflammation did not arise from endometritis, but from tubal disease; he thought that we no longer needed to sacrifice all of these parts when only one form of anatomical structure was seriously at fault. The suppurating fallopian tubes were the particular anatomical structures at fault, and he advised, as a matter of routine, their exsection, leaving the uterus and ovaries with the patient. If an ovary was abscessed it should be removed. If both ovaries were abscessed and the patient far from the expected menopause, the larger should be removed, but the smaller one incised, disinfected with carbolic acid, and left *in situ*. The complaints arising from the existence of endometritis often ceased after simple exsection of double pyosalpinx; if the symptoms of endometritis continued and greatly harassed the patient, the uterus might be removed by vaginal section. The price of removal of the uterus in every case of double pyosalpinx might be partly estimated by the following results: First, loss of menstruation in every instance. Second, partial or complete extinction of the sexual quality in a large proportion of the cases, together with incomplete physical capacity for sexual participation. Third, injury to the nervous system of the patient, arising from her knowledge and appreciation that she had been prematurely and possibly unnecessarily deprived of these and other qualities which rendered her physically and, to a certain extent, morally inferior to other women.

Discussion: Should the Uterus Be Removed When the Ovaries and Tubes Are Removed in Cases of Double Pyosalpinx, When Operating through Either the Abdomen or the Vagina?—Dr. I. S. Stone of Washington presented this communication; he said that it was beyond question that gonorrhœa was responsible for the vast majority of these pus cases; the mucous lining of the uterus transmitted the microbe and bore the brunt of the attack, rather than the muscular structure of the uterus. Hysterectomy was unnecessary unless it could be shown definitely that the organ was the seat of deep-seated abscess or equally dangerous conditions, which continued to endanger the patient's life and caused persistent and annoying symptoms. No organ should be removed unless absolutely necessary. In a large majority of cases the pus found in diseased annexa was sterile; it followed that the chief element of danger from sepsis was eliminated, and the uterus was not the seat of dangerous microbic infection. The exception to the above rule might be found in puerperal infections. When purulent annexa were removed, the uterine cornua should be excised, and the uterus permanently sealed, and thus made a barrier against further infection, and also to permit effective treatment addressed to the uterine cavity, if necessary. Hysterectomy required additional time, caused further traumatism, and necessitated changes in the anatomical relations of vagina, bladder, etc. If necessary to drain the pelvis by way of the vagina, the usual route through the cul-de-sac posterior to the uterus, answered every purpose. Finally, a number of women objected to panhysterectomy, and besides, the question of its effect upon the mental status of the patient was *sub judice*.

Dr. Matthew D. Mann of Buffalo read a paper on the same subject. He believed in the necessity of saving the tubes, and particularly the ovaries, especially in young women; but here we presupposed that the ovaries and tubes must be removed, and the question related solely to the "emasculated uterus" and all thought of retaining the sexuality or fertility of the woman was laid aside. He operated by the abdomen, rather than by the vagina. The almost sole cause of pus tubes was gonorrhœa, though there might be a mixed infection. The uterus was usually infected and might make trouble afterward, and be the cause of spreading the infection. The uterus was no longer of any use. Menstruation did not always stop after removal of the tubes and ovaries, and if it remained it might become excessive and cause trouble. It might become the seat of cancerous disease. In acute infection, removal of the uterus afforded the best means of securing drainage. The results of the vaginal route where the uterus was always removed, warranted its removal by the abdominal route. The woman's sexual life was unaffected by the removal of the uterus. The additional time taken for its removal was more than counterbalanced by the securing of good drainage.

Dr. Charles P. Noble of Philadelphia presented a paper on the same subject. He said that the superiority of hysterectomy over the removal of the uterine appendages for pyosalpinx and abscess of the ovary consisted not only in its lower mortality but in its lower morbidity. When hysterectomy was done, the four arterial trunks supplying the pelvis were ligated, so that the control of oozing was much better. When the appendages were removed and the uterus left, the posterior surface of the broad ligament and more or less of Douglas's pouch was left raw and oozing; it was difficult to control the oozing points by ligature, and the result was that drainage was more often required; or, on the other hand, intraperitoneal exudate more often resulted. When hysterectomy was done, this oozing surface was largely removed, and what was left of it was covered over by the comparatively healthy peritoneum from the anterior wall of the broad ligament and bladder. There was one group of cases in which the pus was seldom infected and in which, with a clean technique and the thorough arrest of oozing hemorrhage, the pelvis could be left after the operation of hysterectomy in a fairly normal condition, thus avoiding the necessity of drainage and the various post-operative complications inherent in that method.

Dr. Gordon of Portland proposed the query: When Both Ovaries Must Be Removed, Should the Uterus Be Removed? In 75 per cent. sexual function was improved; in 20 per cent. it was not changed; in 5 per cent., possibly, it was abated. It seemed absurd to leave a functionless organ after the tubes and ovaries had been removed. In gonorrhœa there was left an infected organ with two arteries pumping into it, which made it a focus of congestion and pain; he saw no reason for leaving the uterus. He didn't believe that the ovaries were the seat of sexual functions. The ovaries had little to do with sexual desire. That depended on something else. He protested against the conservation of this useless organ. It would have to be removed to relieve the patient.

Dr. Bache Emmet of New York said that in many cases the uterus had not been infected as well as part of the tube. The pus was also often sterile. In some cases the uterus was a decided benefit in maintaining some degree of menstruation. He believed that in pendulous abdomen the uterus would form some point of support for the abdomen. In disease of the uterus it should always be removed. After the uterus was removed the atrophy of the vagina would cause great trouble. It would cause pain in sexual relations.

Dr. Bovée of Washington believed that it depended greatly upon the condition of the uterus as to whether it should be removed when the tubes and ovaries were removed. He removed it more for adhesions

and not so often for infection; the additional traumatism incident to the removal of the body was not important. He rarely removed the cervix; in removing the cervix the vagina was shortened, which was a disadvantage.

Dr. Reamy of Cincinnati did not believe that the ovaries were the seat of sexual desire, except in so far as the physiological harmony was considered. If it were necessary to save life by removing the uterus, then the organ should be removed. The uterus was not an unimportant organ.

Dr. Dudley of New York said that this was only a revival of the old discussion; sexual instinct was due to a combined action of the entire organism. In cases of double pyosalpinx it was wise to remove the uterus when the pyosalpinx was of septic origin. The patient could have gonorrhœa after the removal of the uterus, for she could have vaginitis, rectitis, etc. There were cases of pyosalpinx without infection, from cold. He thought that the chief cause of septic pyosalpinx were, first, from abortion, next from gonorrhœa.

Dr. Arthur Johnstone of Cincinnati believed in the persistence of sexual functions after the removal of the organs, as long as spinal cord and vagina and clitoris were left. True, cirrhosis of the vagina came from neglect of vaginitis. The vagina in this trouble should be treated as carefully as was the eye in trachoma. He believed that vaginitis was due to the pathological condition and not to the removal of the organ.

Dr. Stone of Washington did not believe in removing the uterus for procidentia; there was no real existence of gonorrhœa in the uterine walls, it was endometritis.

Dr. Noble said that many pus tubes were due to criminal abortion or to infection in childbed; infection played a definite rôle. He believed in drainage. There were fever deaths and better recoveries from radical operations. We were through with conservative operations for pus cases; conservative operations on the ovaries was a different matter.

Dr. Harris of Paterson said that in a considerable percentage the sexual instinct was decreased after the removal of the ovaries.

Ureterocystotomy.—Dr. J. Wesley Bovée of Washington narrated the history of this operation, pointed out the indications, discussed the diagnosis, routes and methods of operation, complications, technique, and after-treatment. He then detailed histories of cases, with results.

Dr. George H. Noble of Atlanta, Ga., spoke of bladder drainage. He liked a permanent catheter; he fixed the ureter without tension into the bladder and made a tight joint. He folded up the bladder about the ureter in order to make it tight.

Dr. Polk said that bladder implantation would eventually lead to stricture. He believed in the end-to-end junction and through-and-through suture.

Dr. Peterson of Ann Arbor reported a case in which he put the ureter into the bladder; the patient died a few days later; the operation was more or less dangerous.

Note on the Occurrence of Gallstones in Insane Women.—Dr. W. P. Manton of Detroit said that gallstones were of very frequent occurrence among insane women. The causes were difficult to determine. He discoursed on autopsy findings in these cases.

Excision of the Proximal Ends of the Fallopian Tubes at Their Origin in the Uterus, the Operation of Choice, for the Extremely Rare Cases Wherein Sterility Is Desirable.—Dr. Philander A. Harris of Paterson gave a description of the operation of sterilization. He made an elliptic incision into the uterine cornua, rather closely encircling the tube. He passed a hook beneath the tube, and while lifting it with gentle tension, severed its lumen as near to the uterine mucosa as possible. He closed the chasm in the uterus with interrupted small catgut sutures. He scarified the small area of peritoneum at a point on the upper posterior aspect of the fundus uteri nearby, but not endangering or involving the sutures which closed the chasm. He flattened the cut end of the fallopian tube and attached it to this denuded surface with two or three fine catgut sutures. The other tube was, of course, treated in a similar manner; the route of approach to the field of operation might be made through the ordinary median line suprapubic incision or from the vagina between the bladder and uterus. The only operation of this character which he had performed was done by the vaginal route, which he regarded as the preferable one for such operators as were experienced in infrapubic sections. The speaker then described the secondary operation for the cure of sterility affected by the primary operation above described. He concluded by saying that he thought there was necessarily but a very, very limited field for the legitimate employment of this or any other operation which rendered a woman sterile. If, however, sterility was proposed, and sanctioned, he believed that exsection of the proximal ends of the fallopian tubes was the easiest, safest, and most desirable proceeding for effecting that result. To sum up the subject, this was to take the place of the Porro operation; to take the place of bilateral removal of the ovaries; to take the place of bilateral excision of healthy tubes. Menstruation would not be sacrificed. Every advantage arising from retention of the ovaries would be preserved to the individual, excepting the single item of impregnation. Tubes thus disconnected from the uterus would probably remain immune from future gonorrhœal infection of the endometrium. A patient thus sterilized could doubtless be cured of her sterility by implantation of the tubes through the uterine cornua to the uterine cavity. While there were doubtless cases which were characterized by certain conditions of the body, mind, or nervous system, calling for the voluntary production of sterility, there must necessarily be a very limited field for the employment of this operation. If a case was to be surgically sterilized it should be effected in such manner that the patient and her friends might feel that she could be restored to fertility should the pathologic factors of her case so abate or disappear, as to render impregnation and pregnancy permissible. No attempt was made to present the indications for an operation which produced sterility for temporary purposes, although such instances were believed to be within the range of possibility, and if so, they emphasized the advantage of doing the primary operation in the manner proposed.

Dr. Bissell reported a case; the patient had a justo-minor pelvis. When he reached the patient in her first labor, the child had been dismembered, the head being left in the uterus; at the second pregnancy Cæsarean section was suggested; labor was brought on at eight and one-half months. The child could not come through the natural passages. Cæsarean section was performed and the child soon died. At the third pregnancy Cæsarean section was performed, and the patient asked to be sterilized; the speaker exsected the tube from the uterus, opened the broad ligament and anchored the tube. He said that every normal tissue in the body should be preserved; it was preferable to sterilize a woman and tell her there was a possibility of her becoming pregnant.

Personal Experience in Operations upon Diabetic Patients.—Dr. Charles P. Noble of Philadelphia said that of the seven patients operated upon by himself, six made good recoveries, and one died of diabetic coma. In the six remaining cases the healing of the wounds and the general progress of the patients toward recovery was not different from that in patients not the subject of glycosuria. In looking up the literature of the subject, he was able to add to his own list sixty-two cases of operations upon diabetics, upon those organs of the body which were the special field of the gynecologist and abdominal surgeon, making a total of sixty-nine cases. Of the sixty-two, there were fourteen operations upon the female breast, thirty-one operations upon the female generative organs, and seventeen abdominal operations other than on the generative organs. Of the sixty-nine

patients, fifty-two recovered, and seventeen died—a mortality of 24 per cent. Of the seventeen deaths, one was from erysipelas, two from sepsis, five from causes not stated, and nine from coma. A careful reading of the reported cases would indicate that the proportion of deaths from other causes than coma was not extremely high. The chief cause of death after operations upon diabetics was coma, and apparently this result was the one which was the least possible to guard against. His first operation on a diabetic was an accident; the urine from two patients to be operated on the same day was mixed in the laboratory, the supposed diabetic was refused operation and the patient supposed to have normal urine was operated upon. The error was not recognized until the following day. This patient made a good recovery from the operation—removal of the breast, except that there was suppuration in the axilla, due to a sponge left high up in the axilla. The favorable course in this case was a factor in inducing him to operate upon the subsequent cases. His rule was to postpone operation if there was more than .2 per cent. of sugar present in a total excretion of three pints per day. The contraindication to operation was strongest in those patients suffering markedly from the constitutional symptoms of diabetes —poor nutrition, wasting, intense thirst, and morbid appetite.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held April 21, 1903.

LEWIS A. CONNER, M.D., CHAIRMAN.

A Case of Complete Obstruction of Both the Superior and Inferior Venæ Cavæ.—Dr. ALFRED MEYER reported this case. (See page 806.)

The Nature, Frequency, and Possible Significance of the Various Forms of Epileptic Aura.—Dr. WILLIAM P. SPRATLING of the Craig Colony for Epileptics was the author of this paper. He said that the word "aura" originally meant a vapor emanating from, or surrounding the body, but this narrow meaning had been greatly broadened in the use of the word to indicate the warning of an epileptic seizure. It was now believed that the aura originated in the central nervous system, and was referred to the periphery. In recent years there had been a growing tendency to look upon the aura as essentially constituting a part of the epileptic attack, and, in the opinion of the speaker, this was justifiable and reasonable. The various auras could be best studied by grouping them under four heads, viz., the psychic, the sensory, the motor, and the irregular. Perhaps those of a sensory nature were of the greatest importance because they far outnumbered the other varieties. Out of 815 males and 510 females studied with reference to the aura, 319 males and 186 females had a sensory aura. A psychic aura was present in 4 per cent. of the cases, and a motor aura in 2 per cent. Some form of aura was present in 589 out of 1,325 cases, or 45 per cent. It would be safe to say that 50 per cent. of all epileptics presented an aura. It was impossible to estimate the number of cases in which the irregular auras were present, but they were by no means common. A psychic aura might make its appearance in a certain abnormal mental state and leave its impression upon the brain. The most common form was a sudden acceleration of the imagination. In some instances this was preceded by some confusion of ideation. Fear, of a primary and unreasoning kind, was often met with in connection with psychic auras. The question arose as to how this fear was artificially induced. Warnings, taking the forms of ideas, were usually dependent upon sense conceptions, especially of vision. Sensory auras partook of the greatest range of character. Visual auras greatly predominated, and usually took the form of flashes of light. Sometimes they took the form of optical illusions, though still more rarely a temporary blindness might usher in the attack. Sometimes there were flashes of colors; sometimes surrounding objects appeared to be greatly magnified for a few seconds before the attack. When color only was seen it was apt to be either red or blue. It was interesting to note that red, which was oftenest seen, had the smallest retinal field. Occasionally auditory and visual auras were associated. Auditory auras were usually roaring voices, sounds, as of the waves of the sea, and buzzing noises in the head. The epigastric aura was more common than all the other sensory auras combined. It was present in 200 cases, or 15 per cent. The first and most common form was an annoying sensation in the pit of the stomach. A second form was a deeply seated burning pain, and a third was a choking sensation, which rose until the throat was reached, when consciousness was lost. It was a most important problem to determine whether the original disturbance was to be sought in the respiratory center primarily, or whether it lay somewhere in the periphery, as in the stomach or heart, or especially in the circulation. Many cases exhibiting the epigastric aura suffered from indigestion. One of the most common forms of motor disturbance was that of running before the onset of the attack, and such patients were apt to become violent. Some epileptics turned around two or three times before the attack. The author said that his experience had taught him that the more sudden and complete the epileptic attack the less likely it was to be preceded by an aura, while the greater the departure from the ordinary type the more likelihood there was that an aura would be present.

Dr. WILLIAM M. LESZYNSKY said that it was important to study the initial manifestations of an epileptic attack. Where there were motor phenomena preceding the attack one should be careful not to confound Jacksonian epilepsy with true epilepsy. An aura was really a warning of which the patient was cognizant, whereas objective phenomena preceding the attack were not usually classed as auras. It often required much patience and careful observation to determine the existence of an aura. It was only very exceptionally that one could accomplish anything by treatment begun as soon as the aura appeared In every instance the patients had been maniacal in the beginning and were conscious of it, but could not control it.

Dr. L. PIERCE CLARK said he believed the aura of epilepsy was always sensory or psychosensory at bottom, a fact which was quite in accord with the contentions of Dr Prout and himself as to the pathology of the disease. Epilepsy was essentially a sensory phenomenon with a motor manifestation. He did not believe, however, that the aura of the fit began in the peripheral portion of this highly complex reflex arc of the cerebral cortex, but rather in the sensory type of cells of the cortex. A disturbance of these cells in the fit caused both a peripheral sensory projection, constituting the aura, and, later, an excitation, or better, a withdrawal of inhibition over the motor cells immediately engaged in the epileptic convulsion. There would be some sort of aura in every case of epilepsy if the rate of cerebral diffusion of the discharge were slower or less complete in range. Thus, there was retention of consciousness until very late in the fit in hemi- or monospasm. and in those convulsions, spreading slowly over the entire body, in which there was a leisurely order of muscular march of the fit, Jacksonian in type but general in effect. The explanation for the great frequency of one type of aura over that of rarer forms appeared to him to rest upon the degree and extent of the area such sensations possessed in the cerebral cortex, as was particularly well shown in the frequency of the abdominovisceral type of aura. In primordial life the greater portion of sensory impulses clustered about the gastrointestinal tract; hence, its wide representation in the human cortex and its frequent central disturbance in the disintegration

of this organ in epileptic fits. The length of time the aura lasted and its degree of elaboration showed the degree of reluctance of the other cerebral centers to participate in the fit; in other words, the longer and more elaborate the aura the less inclined apparently was the cortex to engage in the epileptic explosion. Many epileptics, on the point of recovery, had only the aura of their former grand mal fits; hence, the criterion for best prognosis in the surgical treatment of traumatic cases was found in those cases in which the aura consisted of a sensory disturbance in that part or extremity which would be engaged later in spasm and, when the seat of cranial trauma was over, that corresponding motor area involved in the fit.

The Aura and Preventive Treatment.—Dr. Clark then exhibited a neat and convenient bottle which he gave to such patients as were able to employ amyl, ammonia, or smelling-salts to advantage in warding off individual attacks, especially minor ones. It possessed many advantages over the "pearls" or bottle which, because of their awkward shape were not kept ready for instant use.

Intellectual Aura — Continuing, the speaker mentioned briefly the rather rare intellectual aura and reminiscent dreamy state, citing two cases, both of severe and long standing grand mal. The first patient described the warning as coming on like a dream, surrounding objects appearing familiar but dim and distant. Thi state lasted one or two minutes without any outward change in the patient, who meanwhile sat in deep and pleasant reverie. The second patient described a very similar state in which, though the surroundings were familiar, the place could not be located. There was a "dreamy luxury" associated with this aura, which preceded every epileptic seizure. Twice in this patient's whole experience the aura occurred but no attack followed. Dr. Clark said that possibly the more or less marked mental diplopia of the Buddhist or shinto devotee, the remembrance of a former life cycle, might be an analogous mental state to that of the intellectual or reminiscent aura of epileptics and the hypnotic state. The intellectual aura must not be confounded with the ordinary visual aura. Jackson plausibly contended that such epileptic discharges were probably in the purely psychic areas, particularly in the highest represented centers in the frontal and temperosphenoidal lobes.

Dr. Thomas P. Prout said that it was through studies of the aura that epilepsy first came to be regarded as a cortical disease. Epilepsy was certainly a sensory disease with a motor manifestation, and was due primarily to the irritation of sensory elements lying in the cortex. The motor manifestations were apt by their prominence to overshadow the other portion. The work of the past five years had done much to give a foundation for a correct understanding of epilepsy. After severance of the pyramidal tracts in dogs and monkeys on both sides it had been found that the motor phenomenon could be induced by irritation of the cortex. If the cortex were painted with cocaine, the pyramidal tracts being intact, no convulsion could be produced. From this it was concluded that sensory elements of the cortex must be irritated in order to develop the fit, and that the fits developed in tracts which transmitted motor reflex impulses. The correctness of these experiments had been vouched for by a number of investigators. The particular element of the cortex most seriously involved appeared to be the cells of the second layer, cells which were distinctly sensory in type. A study of the sensory side of epilepsy was almost sure to throw much light upon the nature of this disease.

Dr. E. H. Williams said that some years ago he had investigated a number of cases with reference to the urine, but had been unable to detect any difference in the urine at the time of the seizure and of the urine for several hours before and after the seizure.

Dr. Ira Van Gieson referred to a case in which there had appeared to be two different auras—one, a sensation of dizziness, and the other the perception of a black vapor or cloud approaching.

Dr. Louise G. Robinovitch was of the opinion that we did not yet know what constituted an aura. In one case, there was preceding the attack an irresistible impulse to bite children. The patient was an alcoholic and a degenerate. She looked upon this as the result of a temporary paralysis of the frontal lobes, those in which were situated the centers which inhibit the sensory centers. She was of the opinion that during an aura there was, for the time being, a paralysis of the frontal lobes, possibly as a result of a toxæmia. She believed that no matter what the nature of the aura the psychology in every instance was the same. The exhilaration manifested occasionally in the form of an aura seemed to her to be akin to that observed in general paresis. It had been said that persons of low intelligence were more apt to have an aura; the reason for this was perhaps to be found in the fact that these patients were apt to be degenerates and their nervous systems were more easily rendered unstable by a certain degree of toxæmia. Cases of unilateral aura also went to confirm what had been said about degeneracy in relation to aura.

Dr. Spratling, in closing, said that bromides were too often given in a way which masked the important symptoms of epilepsy, among others the aura. His paper had dealt with what could be seen rather than with what the patient felt. They were making some observations at the Craig Colony at the present time with regard to the condition of the urine, but the research was not sufficiently far advanced to warrant the drawing of any conclusions.

The Toxic Actions of Urotropin.—Dr. Warren Coleman read this paper. He said that urotropin was a product resulting from the action of formaldehyde on ammonia. Toxic symptoms were not infrequently noted under a daily dosage of fifteen grains, and individuals differed very greatly in their susceptibility to it. According to Keyes, this susceptibility varied in the same individual at different times. Urotropin was quickly absorbed and eliminated, the rapidity of its complete elimination depending upon the dosage. Apparently urotropin was not ordinarily decomposed in the blood. Formaldehyde could not be demonstrated in the urine of persons taking urotropin, yet clinical experience showed that it possessed a distinctly antiseptic action on the urine. One observer had maintained that acid urines apparently produced a partial decomposition of the urine. Whatever might be the action of urotropin it was the most powerful urinary antiseptic in our possession. It was nevertheless quite irritating to the urinary passages, according to Keyes. Many clinicians did not share this opinion. Urotropin acted also as a diuretic and as a solvent of uric acid. While urotropin was being administered it was common to note some irritation of the stomach and some slight malnutrition. Diarrhœa and abdominal pain were observed in a few cases. One case had been reported in which the skin became irritated and resulted in the development of an eruption somewhat resembling measles. These phenomena disappeared promptly on stopping the urotropin. Headache and ringing in the ears had also been noted. Albuminuria had been produced experimentally in rabbits by the administration of urotropin. Irritation of the bladder manifested itself under two forms, strangury and cauterization of raw surfaces. Bladder irritation was perhaps the most common of the toxic effects of urotropin. The tendency to irritation of the bladder depended partly upon individual susceptibility, but largely upon the size of the dose. When sufficiently severe it was associated with the passage of bloody urine. There were at least seven cases on record of hæmaturia resulting from the use of urotropin.

Dr. Coleman then reported the following case: The

patient was a woman of seventy-three years suffering from pneumonia. Just as the lung was clearing she complained of pain in the bladder and of frequent micturition. The vesical irritation gradually increased in intensity, and in eleven days the urine became turbid. She was given 7½ grains of urotropin dissolved in half a pint of water. In a few hours she developed strangury, and in 17½ hours the urine was deeply blood-stained. Through a misunderstanding a second dose was given, with the result that the urine became very markedly bloody and contained pus and blood cells with a large amount of mucus. Bacteriological and cystoscopic examination were impracticable in this case. The urotropin was stopped, and then there followed a curious paroxysmal hæmaturia for some days. After some time one more dose of urotropin was given, and this was quickly followed, as in the first instance, by strangury. hæmaturia, and hæmoglobinuria. The disappearance within twenty-four hours seemed to warrant the conclusion that the urotropin was responsible for this condition. The disappearance of the hæmaturia and its return on the ninth day and persistence for six days he would explain by the supposition that there was an ulcer of the bladder. This assumption was reasonable because of the great suffering experienced by the patient whenever the bladder was irrigated. It was found that the intravenous injection of formaldehyde into a healthy subject in quantity sufficient to make a 1-to-100,000 solution in the total blood of the body, gave rise to strangury, hæmaturia, and hæmoglobinuria. In spite of the toxic effects noted, it was the general clinical experience that urotropin was very liable to give rise to these ill effects.

Dr. James Pedersen commented upon the uncertainty of action of urotropin as a urinary antiseptic, even in the same individual. He had noted its diuretic action in a limited number of cases. In about a half dozen cases he had observed some irritation of the bladder, a mere burning sensation without strangury. He had never seen hæmaturia or hæmoglobinuria or pain in the kidney as a result of the administration of urotropin. His custom was to administer the drug in a dosage not exceeding thirty grains a day and given preferably in doses of five grains.

Dr. E. L. Keyes, Jr., said that urotropin was so commonly used that the profession generally should fully appreciate its power to produce irritation. He had noted almost every form of irritation except hæmaturia and hæmoglobinuria. He had sometimes given as high as eighty or ninety grains a day in order to conquer a bacteriuria, and had then reduced the dose. Some persons had stood this dosage very well, yet he had observed irritation produced by five grains of the drug given three times a day. He always warned the patient to look out for irritability of the bladder, nausea and diarrhœa, the commonest forms of irritation caused by this drug. He had encountered unfortunately a few cases in which general practitioners, in treating mild cases of prostatic hypertrophy, had increased the dosage of urotropin as the patient's irritation became greater, thinking it due to decomposition of urine. All symptoms of irritation quickly disappeared on stopping the urotropin.

Dr. Louis Faugères Bishop remarked that he had very frequently prescribed urotropin but had not observed any toxic symptoms.

Individual Vaccination Stylet.—Dr. Frederic Griffith exhibited an ingenious little instrument, the invention of Dr. Mareschal of Paris. He said that his attention had been first called to its value by a ship surgeon on one of the Atlantic liners, who was required to vaccinate many hundred immigrants on every trip. Owing to the difficulty in managing seasick persons, this work was always done on the first day out. With the aid of two stewards to "load" the instruments and line up persons to be vaccinated, it was possible to vaccinate from 800 to 1,400 immigrants in a single day The instrument itself resembled a penholder with a spring for throwing out the "pen" after it had been used. In employing the instrument the point was dipped into the vaccine virus and then used to make a cross-shaped scarification upon the arm. By pressing the spring in the handle the point was thrown out, and a new one could then be quickly inserted ready for the next vaccination. The method was inexpensive, the instrument and a supply of 100 points costing apout two francs, or fifty cents. So far as known no dealer in this country kept them, but they could be procured of the manufacturers, in Paris

Book Reviews.

Tuberculosis. By Norman Bridge, A.M., M.D., Emeritus Professor of Medicine in Rush Medical College, Member American Climatological Association, etc. Pp. 302. Philadelphia and New York: W. B. Saunders & Co., 1903.

This volume comprises the lectures given by the author during the last three years, certain statistical matter being added. The bacillus tuberculosis is first described, then the tuberculous process, forms of the disease, etiology. symptoms, signs, diagnosis, prognosis, and treatment. Special attention is devoted to the prophylaxis of the disease, and at the same time the author has judiciously discussed the matter of the practical care and management of those afflicted with its non-surgical forms, and emphasis has been laid on the matter of protecting the community from the spread of infection.

It is always somewhat of a risk to place a medical book in the hands of the laity. In the present instance, when the anti-tuberculosis crusade is being waged so vigorously and when the aid of the laity is being so strenuously invoked, it is well at times to be able to recommend a book which is thoroughly scientific and yet one which can be understood by the average intelligent patient. Such a book, we think, this is, and we congratulate the author on the result of his labors.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and Other Topics of Interest to Students and Practitioners by Leading Members of the Medical Profession throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, with the Collaboration of John B. Murphy, M.D., Chicago; Alexander D. Blackader, M.D., Montreal; H. C. Wood, M.D., Philadelphia; T. M. Rotch, M.D., Boston; E. Landolt, M.D., Paris; Thomas G. Morton, M.D., Philadelphia; James J. Walsh, M.D., New York; J. W. Ballantyne, M.D., Edinburgh, and John Harold, M.D., London, with Regular Correspondents in Montreal, London, Paris, Leipsic, and Vienna. Philadelphia and London: J. B. Lippincott Co. Vol. III, Series 12th.

The present volume of International Clinics is even of higher standard than the preceding numbers of this series. The book is somewhat larger than heretofore, and the quality of the illustrations is better, both with regard to mechanical reproduction and to their value as aids to the text. The different articles are especially lucid and contain information of practical nature, and, as a rule, cover all of the essentials of the subject treated.

The monograph on Blood, by Dr. Thomas R. Brown of Johns Hopkins Medical School, is especially worthy of mention as containing, in a limited space, a fund of information, practically including the whole field of blood research, augmented with an extensive bibliography, which renders the whole a nucleus on which can be reared an extended and exhaustive study of the blood, and all of the special branches thereof.

The article on Abdominal Diagnosis is notable for calling attention to points on the distribution of the nerves, which have an important bearing on the subject, and have been neglected by most practitioners.

On the whole, the volume should prove of great benefit to those who are called upon to be fairly familiar with most branches of medical science, and who require short and concise articles containing the salient points of the different subjects brought up to date.

The Prize Essay on the Erection of a Sanatorium for the Treatment of Tuberculosis in England. Together with a Preface by the Chairman of His Majesty's Advisory Committee, a Number of Appendices, Illustrative Plans, and a Bibliography. By Arthur

Latham, M.A., M.D., Oxon., M.A. Cantab; Assistant Physician and Lecturer on Practical Medicine at St. George's Hospital; Assistant Physician at the Brompton Hospital for Consumption and Diseases of the Chest; Formerly Physician to Out-patients, Victoria Hospital for Children, and Radcliffe Traveling Fellow in the University of Oxford; in Association with A. William West, Architect, Honorary Deputy Treasurer of St. George's Hospital. London: Baillière, Tindall & Cox, 1903.

The essay before us was written in competition for the prize offered by King Edward VII for the best exposition of the principles and details appertaining to the erection of a model and modern sanatorium. The author is to be congratulated in that he has, together with his associate architect, produced a work which will be an excellent guide to those interested in the building of sanatoria adapted for consumptives. The first part of the work is apportioned to the principles which underlie the details which are given later on. The author weighs the advantages of the single and the several detached buildings, and concludes that the latter is, from a medical standpoint, the better. The plans, however, can be adjusted to the more economical method if necessary.

Not only are all the details of the building given in careful detail, but the surrounding grounds and their appointments are also considered.

A large portion of the text presents statistics of the results, both seasonal and general, obtained at various institutions, the class of cases treated, the types of construction, ventilation, aspect, heating, sputum disposal, methods of disinfection, sewage disposal, etc. In addition to the very valuable text there are nearly two dozen ground plans, diagrams of shelters, etc., which serve to give the architect's views on the subject which has become of universal interest.

An excellent bibliography completes the essay, which can serve to give additional information to those seeking further data. We consider the ideas expressed as thoroughly modern, and the instructions given as eminently safe.

A Manual of Materia Medica and Pharmacology. Comprising All Organic and Inorganic Drugs Which Are or Have Been Official in the United States Pharmacopœia, Together with Important Allied Species and Useful Synthetics. Especially Designed for Students of Pharmacy and Medicine, as Well as for Druggists, Pharmacists, and Physicians. By David M. R. Culbreth, Ph.G., M.D., Professor of Botany, Materia Medica, and Pharmacognosy in the Maryland College of Pharmacy; Professor of Materia Medica and Pharmacognosy in the University of Maryland Medical and Dental Schools. Third Edition, Enlarged and Thoroughly Revised. Philadelphia and New York: Lea Brothers & Co., 1903.

This excellent work anticipates the forthcoming pharmacopœia, in being based upon the already outlined list of drugs and preparations to be included in that official guide to the pharmacist and prescribing physician. The recapitulation tables at the end of each section, a very useful feature of the book, contain the names, source, and preparations of all these official drugs. For the benefit of those not familiar with previous editions it may be noted that Dr. Culbreth bases his classification of drugs upon their Sources rather than upon their physiological action or therapeutical uses. Thus, the book is divided into various sections treating respectively of organic drugs from the vegetable kingdom, organic drugs from the animal kingdom, inorganic drugs from mineral kingdom, organic carbon compounds, and non-pharmacopœial organic compounds. There is also a section on the microscope and its uses in the study of drugs. The illustrations are numerous and beautiful, every plant and its official parts, the sources of the animal drugs, and even the crystals of such drugs as occur in that form are depicted. The work is one on materia medica solely and does not deal at all with therapeutics. The present edition has been revised and in part rewritten to make it conform to the new pharmacœpia.

A Textbook of Pharmacology and Therapeutics, or the Action of Drugs in Health and Disease. By Arthur R. Cushing, M.A., M.D., Aber., Professor of Materia Medica and Therapeutics in the University of Michigan; formerly Thompson Fellow in the University of Aberdeen and Assistant in the Pharmacological Institute in the University of Strasburg. Third Edition, revised and Enlarged. Philadelphia and New York: Lea Brothers & Co., 1903.

The *raison d'être* of this treatise is stated by the author to be the bridging over of hiatus which exists between the phenomena occuring in the normal organism and those which are elicited in the therapeutical use of drugs, and the demonstration of how far the clinical effects of remedies may be explained by their action on the normal body, and how these in turn may be correlated with physiological phenomena. "It necessarily follows that the subject is treated from the experimental standpoint, and that the results of the laboratory investigator are made the basis of almost every statement." It must not be supposed from this, however, that the book is solely for the theorist and the cabinet physician, for it is very practical in its scope and contains many suggestions of great value to the physician at the bedside. In this third edition, appearing only eighteen months after the second, some new matter has been added, and such other changes as were necessitated by recent advances in pharmacology have been made.

The Work of the Digestive Glands. By Prof. J. P. Pawlow. Translated into English by W. H. Thompson, M.D., M.Ch., F.R.C.S. London: Charles Griffin & Co.; Philadelphia: Lippincott & Co., 1902.

The present work contains a detailed account of Professor Pawlow's celebrated experiments with regard to the knowledge of the action of the various digestive juices (saliva, gastric-juice, pancreatic secretion, succus entericus).

Pawlow seems to have definitely shown that there exists secretory nerves of the stomach and pancreas. In addition to these special nerves, vasomotor nerves also pertain to these glands. The importance of appetite is well illustrated in the following words which we may cite: "We are therefore justified in saying that the appetite is the first and mightiest excitor of the secretory nerves of the stomach, a factor which embodies in itself a something capable of impelling the empty stomach of the dog in the sham feeding experiment, to secrete large quantities of the strongest juice. A good appetite in eating is equivalent from the outset to a vigorous secretion of the strongest juice; where there is no appetite this juice is also absent. To restore appetite to a man means to secure him a large stock of gastric-juice wherewith to begin the digestion of the meal."

The importance which human instinct plays is well appreciated by Pawlow. The old and empirical requirement that food should be eaten with interest and enjoyment is strengthened by facts obtained from experiments on animals. In every land the act of eating is connected with certain customs designed to distract from the business of daily life. A suitable time of the day is chosen, a company of relatives, acquaintances, or comrades assemble. Certain preparations are carried out (in England a change of raiment is usually effected, and often a blessing is asked upon the meal by the oldest of the family). In the case of the well-to-do a special room for meals is set apart; musical and other guests are invited to while away the time at meals—in a word, everything is directed to take away the thoughts from the cares of daily life, and to concentrate them upon the repast. Heated discussions and serious readings are held to be unsuitable during meal time. In the case of the poorer classes, in whom mental activity is less highly developed, the greater amount of muscular activity and the constant lack of more than sufficient nourishment ensure a strong and lively desire for food in a normal manner without recourse to any special regulation or customs.

Pawlow has shown the important fact that the digestive glands possess the faculty of secreting varied juices according to the nourishment taken, *i. e.* different articles of food evoke a juice with different qualities.

The present volume abounds with new facts and ideas, is interestingly written, and must be recommended in the highest terms to the medical profession.

Cours de Minéralogie Biologique. Sélection et Minéralisation. Spécificité de Minéralisation—Minéralisation et Pouvoir Rotatoire des Sérums. Quatriéme Série. Par J. Gaube (du Gers). Paris: A. Maloine, 1903.

The text of this little manual is presented in two parts and arranged in the form of lessons, seven in the first part and eleven in the second. In his first lesson the author states that mineral matter predominates in organic matter. He takes up various minerals and speaks of their characteristics and the effects of their combinations in the body, and dwells upon the relations between mineral matter and organic matter. He discusses the part taken by mineralization in the acts of natural selection, and speaks of calcium as the metal of construction and magnesium as the metal of reproduction. In the second part he considers the serums and their relation to minerals.

A Compend of Diseases of Children. Especially Adapted for the Use of Medical Students. By Marcus P. Hatfield, A.M., M.D., Emeritus Professor of Diseases of Children, N. W. U. Medical School, Physician to Wesley Hospital, Home for Crippled Children, Chi-

cago Orphan Asylum, etc., Third Edition, Thoroughly Revised. With a Colored Plate. Philadelphia: P. Blakiston's Son & Co., 1903.

Although this is a handbook of only 235 pages, the subjects included are varied, and the text is arranged in a very convenient form. The writer treats first of the anatomy and physiology of the infant, the physiological and traumatic accidents of birth, and septic infection of the newborn. Then follows a chapter on early ailments and hygiene and dietetics of the infant. Various diseases incident to this period of life are next considered—diseases of malnutrition, epidemic and endemic infectious diseases, and diseases of the nervous, respiratory, circulatory, and digestive systems. There is a valuable appendix which treats of various kinds of milk and its modification. This volume is a particularly attractive member of this series.

Biographic Clinics. The Origin of the Ill-health of De Quincy, Carlyle, Darwin, Huxley, and Browning. By George M. Gould, M.D., Editor of *American Medicine*; Author of "An Illustrated Dictionary of Medicine, Biology, etc.," "Borderland Studies," "The Meaning and Method of Life," etc. Philadelphia: P. Blakiston's Son & Co., 1903.

In this attempt at diagnosis, based upon the scanty references of medical import in the biographies and letters of men prominent in their day, Dr. Gould has opened up not only a fascinating field of study for judicial minds, but one in which cranks and faddists may disport themselves to their heart's content and to the entertainment of their not too easily persuaded readers. We hasten to add, lest our meaning be misunderstood, that this observation is altogether general in its application.

Dr. Gould has patiently reviewed and subjected to special criticism the works, published letters, and biographies of the men mentioned in the title, and taken therefrom every reference to the ill-health to which they all were subject in greater or lesser degree. Then sifting and weighing the mass of evidence so obtained, he reaches a diagnosis of the underlying cause of their sufferings. Those familiar with the author's views need not be told that his diagnosis in each and every case is eyestrain. His readers may not, and many, of course, will not, agree with him in his conclusions; nevertheless, we venture to say all will be interested in following his argument and the new reading of the biographies of the illustrious subjects of this study will afford entertainment and sharpen the powers of observation.

Following the diagnostico-biographical section are four chapters on the relation of eyestrain to the general health, which are instructive, though, like the statements of many specialists, whose limited vision hides from them the possible influence of other congenital or acquired abnormalties, they appear to the general reader somewhat extreme in their conclusions.

Compendium der Operations und Verbandstechnik. Von Dr. Eduard Sonnenburg und Dr. Richard Mühsam. Erster Teil. Allgemeine Operationstechnik, Verbandstechnik. Mit 150 Abbildungen im Text. Berlin: Verlag von August Hirschwald, 1903.

This, which is the first part of a work on surgical technique as a whole, is devoted to minor surgery and general considerations on the preparation and application of dressings. It has no points of superiority over the many books on the same subject that have appeared in this country, and in many respects its teachings are at variance with those in vogue here. In particular, the chapters on the sterilization of bands, instruments, ligatures, etc., seem to lack thoroughness, and, as is usual in continental writings, the use of rubber gloves during operations is deprecated. Many of the photographs of plastic dressings are good and several new forms of hip vests, fracture beds, etc., are figured.

Nichtarzneiliche Therapie innerer Krankheiten. Skizzen für physiologisch-denkende Ärzte. Von Dr. Buttersack. Zweite Auflage, mit acht Abbildungen im Text. Berlin: Verlag von August Hirschwald, 1903.

In this attractively written little volume of two hundred pages the subject of non-medicinal therapeutics is presented in satisfactory outline. Much detail is, of course, impossible in a work of this size, but this branch of treatment is still so poorly understood with us that the book ought to find many readers and stimulate further study in the larger manuals. The first seventy odd pages are devoted to a philosophical discussion of the psychology of the sick and the interrelationship of body and mind in sickness and health. The remainder of the book is taken up with the application of light, water, exercise, and air to therapeutic purposes, and the modern methods for their use are described. The various continental baths are discussed, though not all are mentioned, and their special advantages noted and adequate descriptions of phototherapy, medical gymnastics, etc., given.

Erste Ärtzliche Hülfe bei plötzlichen Erkrankungen und Unfällen. In Verbindung mit Dr. E. v. Bergmann, Dr. C. Gerhardt, Dr. O. Liebreich, Dr. A. Martin. Bearbeitet und herausgegeben von Prof. Dr. George Meyer. Mit 5 Abbildungen im Text. Berlin: Verlag von August Hirschwald, 1903.

In view of the widespread popular interest which has followed the movement started by Esmarch twenty years ago, and having for its object the dissemination of knowledge of the measures to be taken in the first treatment of the injured, it is rather surprising that more attention has not been given to this subject in medical literature. The number of first-aid manuals written for the laity, is very large, but this is the first work we know of, intended for the use of the profession. It comprises in the form of lectures on the main subdivisions of the subject concise information as to the treatment of all classes of injuries and contingencies requiring prompt attention, and should prove a most convenient book of reference for consultation in emergencies. The main headings are: The First Aid Treatment of Injuries, The First Aid Treatment in Internal Diseases, The First Aid Treatment in Poisoning, The First Aid Treatment in Diseases of Women and in Obstetrics, and the First Aid Treatment of Coma and Apparent Death. The discussion of these topics is throughout most practical, and the book is one to be of use to all practitioners.

The American Year Book of Medicine and Surgery, being a Yearly Digest of Scientific Progress and Authoritative Opinion, etc., with Critical Editorial Comments by J. M. Baldy, M.D., J. C. Da Costa, M.D., W. A. Newman Dorland, M.D., Geo. Fetterolf, M.D., John H. Gibbon, M.D., V. P. Gibney, M.D., C. A. Hamann, M.D., H. F. Hansell, M.D., Barton C. Hirst, M.D., D. B. Kyle, M.D., Wendell Reber, M.D., J. Hilton Waterman, M.D., under the general editorial charge of George M. Gould, M.D., Surgery Philadelphia, New York, London: W. B. Saunders & Co., 1903.

We are again pleased to see this annual review, which has come to be indispensable to the busy man, now that the number of medical publications is so great. The editors of this volume have evidently expended much effort in examining the surgical and gynecological literature of the year, and in picking out what was considered worth including in the present work, and the result is an important work of reference, the usefulness of which is, however, short-lived. Whatever has attracted attention, as well as much of what might seem of minor importance, is admitted to these pages, and individual opinion is accorded full attention. The illustrations and make-up are good, and numbers of interesting clinical experiences are recorded.

Practical Physiology. By A. P. Beddard, M.A., M.D., Demonstrator of Physiology, Guy's Hospital; Leonard Hill, M.B., F.R.S., Lecturer on Physiology, The London Hospital; J. S. Edkins, M.A., M.B., Lecturer on Physiology, St. Bartholomew's Hospital, and others. London: E. Arnold, 1902.

This manual consists of a series of practical experiments and demonstrations on physiology and physiological chemistry, for students of medicine. The series is arranged in elementary and advanced courses, and lends itself especially to teaching by means of demonstrations and experiments, in which little apparatus is required. The experiments upon the physiology of Muscle and Nerve are based upon the practical courses given at Oxford, and are limited, as far as possible, to those experiments which can conveniently be performed with simple apparatus by a large class of students. The subject of Physiological Chemistry is well covered in an elementary and an advanced course. The Sight receives a very thorough treatment. The list of experiments, at once simple and instructive, is of such a nature that they should attract and interest the student who performs them or witnesses their demonstration. The work is to be commended as a successful attempt to facilitate the teaching of physiology by a method in which the student personally performs or witnesses actual demonstrations, and should prove useful to those practising this method of instruction.

Textbook of Medical Jurisprudence and Toxicology. By John J. Reese, M.D., late Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. Sixth edition, revised by Henry Leffmann, A.M., M.D., Professor of Chemistry and Toxicology in the Woman's Medical College of Pennsylvania, Pathological Chemist to the Jefferson Medical College Hospital, etc. Philadelphia: P. Blakiston's Son & Co., 1902.

The new edition of this well-known work illustrates the

progress in toxicology since the previous edition. The extensive use as household remedies of various synthetic organic bodies has given rise to many instances of poisoning. Phenol and water-gas are now common causes of death, suicidal or accidental. Several new phases of treatment may be noted, such as free washing out of the stomach, the use of alcohol in phenol poisoning, and the applications of potassium permanganate. The long-current belief in the antidotal value of atropine in morphine poisoning is abandoned. The rather over-serious discussion as to the possibility of spontaneous combustion of the human body would seem more in place in a temperance pamphlet.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 6, 1903:

	Cases.	Deaths.
Measles	471	18
Diphtheria and croup	437	52
Scarlet fever	261	29
Smallpox	1	..
Varicella	98	..
Tuberculosis	396	158
Typhoid fever	50	10
Cerebrospinal meningitis	..	9

The Diagnosis and Treatment of Iritis.—A. Maitland Ramsay says that in the treatment of this condition the patient ought to be put to bed in a darkened room, kept on simple diet, and be forbidden smoking and stimulants. The three chief indications to be met are to dilate the pupil, to subdue pain, and to combat the constitutional disorder which is the predisposing cause of the attack. Of all local applications atropine is the one that is indispensable. It puts the iris at rest, and not only relieves pain and intolerance of light, but also by its mydriatic action hinders the formation of posterior synechiæ and tends to break down adhesions which may have already formed. Should it fail to give relief, or its use be followed by exacerbation of pain, examination must be made for increase of intra-ocular tension, and if this be found the drug must be at once discontinued. When the symptoms are severe it is good to combine cocaine and dionine with the atropine, but of even more value are the local applications of heat or cold, and of leaches.—*The Scottish Medical and Surgical Journal*, May, 1903.

Primary Acute Miliary Tuberculosis of the Conjunctiva.—George A. Berry reports a case of this very rare condition. It was undoubtedly primary, and belongs to the first of the four groups into which Sattler classifies this affection, the one in which the disease most closely resembles, both clinically and anatomically, the usual form in which tubercle affects the mucous membrane. The group is characterized by the appearance in the ocular or palpebral conjunctiva of miliary nodules, which have a tendency to break down and coalesce, cause comparatively little surrounding inflammatory reaction, and are uncomplicated by any coxcomb-like or papillary excrescences. In this group there is nearly always swelling of the pre-auricular gland. The microscopical examination shows typical miliary tubercle imbedded in densely vascularized granulation tissue. In the case described the extent of the area of conjunctiva involved, as well as the massiveness of the subjacent hyperplasia, was much greater than anything that has been described elsewhere. The extent to which, and the rapidity with which, the superficial lymphatic system connected with the eye became involved also showed an unusual virulence.—*The Edinburgh Medical Journal*, May, 1903.

Asthma of First Sleep.—Lépine reports a remarkable case of asthma. It occurred in a man of thirty-five years of arthritic temperament, who for six years had had almost every night an attack of typical asthma. The attack would occur during the first sleep at night—when the sleep was deepest. At times when sleep was more profound than usual, the attack was more intense. At times this patient took an excess of alcohol. On the night following, he slept badly, and the asthmatic attack was very light or even did not occur. But the next night when sleep was more profound than usual, the attack was terrible, in fact, so violent that the patient stopped drinking. He also slept on a very uncomfortable bed, inclined laterally. By this means he rested badly and so avoided the attacks to a great extent. He entered the hospital for acute articular rheumatism, and while he was being treated with salicylate of soda the asthma ceased. After the rheumatism disappeared the asthma came back in a light form, but ceased again, either spontaneously or under the influence of atropine. The characteristics of the attacks, and the absence of visceral lesions demonstrated that this was a case of true asthma.—*Lyon Médical*, May 17, 1903.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending June 6, 1903:

INFANTILE INSANITY IN ITS RELATION TO MORAL PERVERSION AND CRIME.*

By ALLAN McLANE HAMILTON, M.D., F.R.S.E.,
NEW YORK.

THE determination of the responsibility of children with criminal tendencies, is, naturally, a matter of some difficulty; and it is of the utmost importance that the investigator should bear in mind the different phases and stages of mental development in early life, as well as certain tendencies which cannot be compared with, or gauged by, the behavior of the adult, as is so often done by those who are disposed to hold the child to a strict accountability for all he does and says that may be considered wrong. The word "moral," as applied to infantile delinquency, is clearly out of place when we consider the imperfect mental organization of the very young individual. In ordinary cases there is, of course, very little use in looking for that exercise of reason and judgment which is so clearly present in the adult, even though in a perverted form, for the offenses of children before puberty are largely unthinking, and imply at best, but a low grade of responsibility. It is for this reason futile to attempt to extort confession, with the expectation of obtaining a valid response, or bringing the child to a realization of its wrongdoing, for vehement argument, expostulation, and threats can only result in eliciting what are, at best, the results of suggestion or will cause the victim to lie for the purpose of escaping the torture of the inquisition or punishment, which is all he is likely to realize. It need hardly be necessary to refer to the many instances when, under fear or suggestion, innocent children have even admitted the commission of the crimes of others. In most cases the offence is often apt to be imitative, thoughtless, performed to satisfy the immediate appetites or demands; or is the result of the excessive egoism which is so prominent during the early years of life; or is associated with a disregard of the future or its consequences. Someone has likened this childish condition of mind to that of the instinctive adult criminal, whose acts often imply a limited responsibility, for in them wrongdoing is the product of the immature mind.

The purposeless vicious acts of children are familiar enough. Pet animals are butchered or mutilated by young subjects who have witnessed the shedding of blood, or who are prompted by mere curiosity, and such acts have no significance for them; the petty thefts of the very young, simply mean acquisitiveness, and an ignorance of the laws of *meum* and *tuum;* incendiarism is prompted by the love of seeing fire and the craze for excitement. Suicide even, need not bring with it any suspicion of mental disease, and cases are reported by Durand-Fardel, in which the simplest disappointment, such, for instance, as the loss of a pet bird or failure to keep up at school, prompted the taking of life in this way. Undoubtedly, this is often due to the ignorance of the meaning of death. The fact that several young criminals are found in the same family may mean nothing, except in so far as imitation, vicious education, and example are concerned,for the police reports constantly show records of family crime of this kind. The Children's Society was recently called upon to take care of the younger members of the Daly family, the head of which was serving a long term in the penitentiary. Five of his seven children, most of them of tender years, were habitually engaged in various forms of theft, though it does not appear that any were insane, but that they had succumbed to the influences of their criminal environment. What future generations of this family may show, may be inferred from the history of the Jukes. On the other hand, all of the offences of childhood may sometimes be clearly marked symptoms of insanity or, at least, of a psychopathic condition. The disordered mental states of children, leading them to the commission of crime, can hardly be said to fall under the head of *adolescent insanity*, which usually appears at puberty, but is rather the expression of the degenerative mental state which precedes that psychosis, and is too disordered and inconstant in its nature to be exactly defined or classified. Certain neurotic children, even as early as the third or fourth year, may develop peculiarities in which ethical and moral defects are present and constant and, for this reason, their peculiarities differ from the occasional acts of sane children. A form of useless lying, with defiance of authority, waywardness, sexual perversion, and intolerance of restraint, as well as cruelty, is nearly always present. The children are dull, so far as systematic work is concerned, but sharp and precocious in other ways. That lying is a symptom of insanity is, of course, well known, but there is a kind of lying among the degenerate that differs from that of the mentally afflicted as well as the normal individual. It is the conscienceless and habitual kind that seems to be objectless as well as unnecessary. It begins in the very young, and, as has been said, is associated with other forms of moral delinquency. The biographer of Madame Humbert, the famous French confidence woman, referring to a little girl whose subsequent enormous swindling transactions were well known, says that her capacity for deception began at a very early age, for when she was only five she would return from a walk of a half hour and declare that she had had hair-breadth escapes and thrilling adventures, and tell of the wild outbursts of male admiration that had greeted her. Madame Humbert herself was a precocious liar and neuropathic, presenting stigmata of degeneracy, and it was a part of her sexual nature to be able to see "those visions which words transform into lies." At the age of thirteen, when Thérèse Daurignac, she forged her father's name and carried hidden securities in her corsets, "obtained, heaven knows where." The history of this creature is full of interest to the student of criminology. In hysteroid psychoses, where lying of a characteristic kind exists, there is a ways a species of limited responsibility.

The records of the Children's Society, which are those most available, are in every way unsatisfactory, one reason being that it does not appear that the children arrested for crime are examined by psychiatrists, unless they are clearly imbecile or

*Read before the Psychiatrical Society, New York, April 1, 1903.

idiotic. Doubtless a large proportion of what are tabulated as "ungovernable children," especially where the parents are insane, would show the existence of some mental weakness, and perhaps, a decided degeneration.

Speaking in this connection of heredity, it is a somewhat curious fact that, in these cases, the mothers are more often insane or intemperate than the fathers, which, I believe, is not in keeping with the ordinarily accepted opinion. While it is the view of some modern writers that actual insanity in the very young is rare, the literature of psychiatry is very rich in these cases, and Esquirol, a great many years ago, reported a large number of interesting examples of mental disease and crime in infants. Since his day, there can be no doubt of the now generally recognized fact, that many forms of

adult insanity are found as well in early life, among them, primary limited delusional insanity or paranoia, paretic dementia, and even circular insanity (Kelp). In fact, the mental disturbance bears a close resemblance to the degree of development, the acquisition and storing up of concepts, and the ability of the child to use them at the particular time of life. It does not do to say that children cannot have delusions, although it is rare for there to be any complex or elaborate false beliefs or series of related delusions, prior to the time when association and selection power are developed to any degree.

The disturbances of ideation usually consist of insistent concepts and resulting compulsive acts, and there does not appear to be any very elaborate association of ideas leading to the formation of a judgment. In an old, but suggestive case, reported by Esquirol, of a little girl of six and a half years, who wished to kill her stepmother as well as her younger brother, punishment had no deterring effect, and she was constantly seeking weapons with which to kill those she disliked. The following interrogatories and answers show the condition of mind to which reference has just been made:

"Why did you wish to kill your mama?"
"Because I do not like her."
"Why do you not like her?"
"I do not know."
"Has she ill-used you?"
"No."
"Is she good to you, does she take care of you?"
"Yes."
"Why do you strike her?"
"To make her die."
"Your blows cannot kill her; you are too small for that."
"I know that. One must suffer before they die, and I wish to make her turn ill, then she may suffer and die, for I am too little to kill her with one blow."

Insane children often have obsessions which are continued. They are rarely talked about, and the impulse is the first evidence of the mental mischief. In but few instances, is there a fear of the tyranny of the dominating idea and its transformation into a dangerous outward expression, and there is rarely apprehension of the consequences. Sometimes the realization of the possible results of the act are tardy and only follow the explosion. In a case of T. F. Fisher's a young boy said to his mother, "I have behaved well to-day, haven't I?" and without further conversation, suddenly threw a stone at her. He was immediately alarmed at her narrow escape, crying out, "Why didn't you dodge it? Why, I might have killed you!" This appreciation of the consequences sometimes exists, but there is none of the dread of the obsession which is so commonly met with in advanced life. In an exceptional case that fell under my observation, the patient being a boy of seven, there was *delire de toucher* and timid doubts. The idea of killing a member of his family was so strong that in his efforts at control and consequent fear, a state of excitement resulted which approached a confusional psychosis.*

In the majority of cases there is an apparent absence of the so-called "moral sense," and especially is this the case when homicides are committed, when the subjects are often boastful, flippant, and have talked callously about the deed. A case was narrated of a boy who drowned a boy smaller than himself, that he "might see the little devil kick in the water."

The Pomeroy case, which C. F. Folsom and other Boston alienists discussed, is an example of this kind, and in taking this for a text, C. F. Folsom divided the criminal insanity of children into five groups, which were: (1) delusional insanity, (2) insanity from masturbation, (3) epileptiform insanity, (4) moral insanity, (5) moral imbecility. This table is open to the objection that these psychoses often overlap each other or are found in association. It is much better to consider insane criminal perversion in the young as due: (1) to idiocy, imbecility, or an epileptic psychopathic condition; (2) to true primary delusional insanity; (3) to a psychopathic state, with a degenerative basis, with delusive ideas and obsessions, and (4) to paretic dementia and other adult mental diseases rarely developing in childhood. It is not my intention to discuss the first division, suffice it to say, that pyromania is exceedingly common among epileptic children, perhaps more so than in any other form or disease, and one case is reported by Meschede, in which, upon no less than three occasions, the child burned buildings, and on another made a murderous assault in obedience to an auditory hallucination.

Paranoia, in young subjects, is for reasons already stated, not so common as the other insanities. Consequently, crime among children, as the result of delusion, is correspondingly rare. I may relate the case of a boy of twelve which, I think, illustrates the

*Cases are detailed by Fisher, one of a boy eight years old, who flayed and cut puppies and chickens, avoiding vital parts. At eleven he shockingly mutilated a child of three by cutting it with a sharp bone, inflicting no less than nineteen wounds and nearly cutting off its right ear. He confessed his misdeeds, and said he could not help them. He was as intelligent as most boys of his age.

manner in which it might occur. I saw the subject first about eight years ago. He came of distinctly neurotic stock, two of his uncles on his father's side and an elder brother having been insane, and confined in asylums. The mother was hysterical, and the father's habits were bad, so far as alcohol was concerned. As a child, he had been exceedingly "nervous," and all his early illnesses had been characterized by a predominance of nervous symptoms. At the age of eight he had chorea, which was temporarily cured, but reappeared twice afterward. He is megalocephalic, and his frontal bosses are prominent. His lips are thick, and his teeth irregular and crowded. He is hypermetropic. His ears are abnormally long, and stand well out from the side of the head. There is a history of onanism, and the

genital organs are larger than they should be in a boy of his age. He has given his family a great deal of trouble, being at times capricious, hypercritical, insanely conceited and cynical, defying authority, and sometimes running away from home. It was difficult to keep him at school, and when there he did not apply himself. He seemed to take readily to mathematics, but other subjects gave him great trouble. As a young child, he had been subject to night terrors and had always dreamt of disagreeable things. He usually manifested a certain degree of timidity, irresolution, and doubt. While at school he conceived the delusion that he was an illegitimate child, and that his father was not his real father, but a certain prominent person was, and the boy's conduct and letters reflected his profound belief in this. After a period of strange conduct, with great reticence and preoccupation, he one day astonished his family by accusing his mother of previous illicit relations with his delusional father, and this naturally led to foolish punishment. From his school he wrote before this, as follows: "It was the idea I was not your son, and the idea almost drove me mad at times. . . . It began about a year ago, a mere fancy at first; I laughed at the idea. I gave it thought and allowed it growth and it got a hold on me, the growth turned into reality, and how I have suffered." He declared that his schoolmates had turned against him because of this; he avoided them, and he attributed their disregard to the knowledge of his doubtful paternity. One boy, he said, had called him a "bastard," and he came home full of enmity toward his mother, and in a very excited way, made the charge. This was evidently an hallucination of memory. He said, in another letter: "I acted badly at times when at home, to see if my doubts would not be confirmed by your lips." In all his letters, which are numerous and which covered a period of several months, his delusion was reiterated, and had obtained complete possession of him. It was only after some time that medical advice was sought, and this was because he had provided himself with a pistol, and had so clearly shown his intention of doing his mother harm, that the family were frightened, and I was called in to see him. He was immediately removed from home, placed under restraint, and it was not until several months afterward that his false belief was wholly removed and he was allowed to return home; but it cannot be said that he is well to-day.

A large number of the reported instances of juvenile crime are in subjects in whom an unstable degenerate state exists, which is often the result of improper environment and unsuitable, improper, or no education at all, when dysphrenia of variable duration may be developed. Sometimes, indeed, it is permanent, and though the conduct of the youthful malfactor is looked upon as carrying with it a certain amount of responsibility, such individuals. develop into dangerous and habitual criminals, who as recedivists, keep our criminal courts busy and crowd the prisons. Born with all the weakness which springs from defective heredity, they become, in congenial soil, precocious, drunkards, thieves, or murderers. No jeremiad is needed to picture the influence of the worst factor of the day—the pollution of the tone of all grades of society by the irresponsible newspapers, which appeal to the ignorant and impressionable. Not only are all ordinary ideals of pure life thus perverted, but social distinctions and standards are upset, envy and covetousness are fostered, and murder and anarchy are encouraged by a disingenuous appeal to a falsely created sense of injustice. In the very young what might be growing principles of a high kind, are nipped in the bud. When the neurotic child is a little older, defiance of society is taught, and a feeling of unrest is converted into a delusion or delusions. The instability of the nervous organization which is present at puberty and increased by excessive masturbation, increases to the extent that a psychosis is formed, possibly with fixed ideas of a pernicious kind.

The celebrated case of Jesse Pomeroy is an apt illustration. Pomeroy had done little else than read dime novels of the most lurid kind in which the heroes were outlaws, and the usual tales of border murder and crime crowded the pages. So powerful was the influence of these books that by a species of auto-suggestion he identified himself with the bloodthirsty hero who had killed his three-score of men and took the names of the most picturesque ruffians, and with his schoolmates enacted the stories, working himself up to a state of fury. The violent episodes were reproduced, boys being tied to trees and devilled. For some time he committed no grave offences, but eventually carried out his brutal ideas by torturing and afterward murdering young boys and girls. One child was found tied to a telegraph pole with his back cut to ribbons, and bearing the appearance of having been rubbed with salt. His

counsel thus summed up the shocking incidents of his life:

"In the Winthrop school in Charlestown, in 1871, he made faces in school. The teacher said that at times it was utterly impossible to make him understand. When reprimanded he would say, 'I could not help it.' He thought it very unjust if he were punished.

"As early as December, 1871, while he was living in Charlestown, he went over to Chelsea and took a strange boy with him to the top of Powder Horn Hill, some two or three miles from where this boy lived, and for no apparent reason or purpose. He stripped the young child, as he did all his victims, and whipped it, making it go through certain acts before him, and then told him to go home. In February, 1872, another act of this kind occurred. Pomeroy left his home, unknown to his parents, and found another boy in Chelsea, also a stranger. He was taken to the top of Powder Horn Hill and there treated in the same way as the first. This was in the winter time and he was put up there in some ice. Pomeroy whipped the boy, stuck some pins into him, and went through a general performance, the details of which are not told, but it undoubtedly was of a sexual character. Again, in July, he took another boy from Chelsea, he still living in Charlestown, for he went from Charlestown to Chelsea; he did not seem to go to any other place. He took that boy up the same hill and substantially went through the same performance with him, whipping the boy more or less, taking off his clothes and making him get upon a stone and dance. In one instance he made the boy say 'the Lord's Prayer,' ending with a vulgar word.

"About the first of August the Pomeroy family moved to South Boston. He had been there but a short time when he commenced the same thing with the boys there, who were utter strangers. On the 17th of August he took a strange child out near some marshes, where a boy named Millen was subsequently killed by him, and there undressed him, whipped him, making him say obscene words, and danced around him. The next occasion was on the 8th day of September, 1872, when he took another boy, repeating the performance as usual. On September 11, three days afterward, he took another strange boy out to the same place by the marsh. The four South Boston boys all went out to the marsh. He went through the usual performance and took out a large knife, which he seemed to have carried in a pocket in his coat, a sort of old butchers' knife that was used about the house, or for carving, wounded and slashed his victim. This boy was the first one that he had cut seriously. He was cut on the head. As he danced around him, and while the blood was on the knife and running from it, he sat and laughed.

"Again on the 17th, six days afterward, he took another victim, also an entire stranger, and tied him to a telegraph post, near the bridge in the vicinity of Chelsea and whipped him. Subsequently, on the 20th day of September, he was arrested. He pleaded guilty and was sent to the State Reform School. There was no proof against him except the statements of smaller boys, and there was some doubt of his guilt in the community. At the Reform School he attempted to use a knife, but was discovered by a teacher. When discovered he said he was not doing anything. At one time a snake was killed in the road. When Jesse saw the blood he wanted to attack the snake again. It was with great difficulty that he was diverted. After that he behaved well and was discharged from the school. He said he would never do a wrong thing again. The first lapse after his release occurred on the 22d day of April. On the 8th day of March he killed a girl named Curran. Jesse at his mother's direction opened her store, which was a small place. He went there at half-past eight o'clock in the morning, and while engaged in sweeping it out the Curran girl came in. She was an entire stranger to him and he to her. She came to purchase an article of some kind. Evidently the thought instantly came to him and he told her to go into the cellar where it was to be found, and then within three minutes from the time the girl descended the steps she was dead. When she went down to the cellar he immediately locked the front door. It is understood that she stepped down and stood in the center of the place below, facing Broadway. He stepped up behind her and in an instant cut her throat. She died quite suddenly without any great struggle. He then took and drew her to one side and covered her over with ashes and rubbish and left the body. She was missed, but no suspicion was aroused as to where she was and no tidings were obtainable. Mr. Robinson says, 'I understand the boy has said, since these matters came out, that he cannot control himself; that if he were out—that is, if he were at liberty—he might do nothing, yet, on the other hand, if the opportunity arose he could not resist.' I once put the question: 'If it was my little boy and I should leave him there, would he be safe?' He said 'No.' He should not mean to do anything, but it did not make any odds whose boy it was. If this feeling came up which he cannot control, and which, he says, is irresistible, he would do these things again."

On one occasion he carried his victim home on a sled, and before killing another, forced him to repeat the Lord's prayer, ending up with a vulgar word. There was much conflict of opinion about this case at the time of the trial, but all of the experts, save one, held that he was insane, and it was recorded as a case of limited responsibility. All admitted that he was weak-minded, that his memory was at fault, and that he was without a clear conception of the horrible nature of his acts. Although possessed of linguistic ability, and regarded as bright at school, he was clearly deficient in other ways and was at times erratic. Many physicians, however, looked upon him absolutely as the product of the pernicious literary influences. Pomeroy had, no doubt, an obsession to kill, which originated in the books he had read, he was a degenerate and a habitual onanist, and probably a sadist. In discussing the case, C. F. Folsom thought there was a motive in his love for torturing, and did not believe that he ever meant to murder. Experience had taught him that, up to that time at least, he could enjoy his horrible sport without undergoing anything that was really punishment to him. Folsom, however, agreed with his fellows, that a psychopathic condition existed.

The very interesting case of Richard Murphy is an example of the dangerous effects of sensational newspaper reading upon a weak and susceptible neurotic boy. I first examined him a short time after his arrival in New York, two years ago, and I believe he was subsequently seen by Dr. Peterson, who expressed an opinion at the time. While there is some doubt about the condition of this subject, and his responsibility, I am thoroughly convinced from several interviews then and within a few months, and from subsequent study of his case, that a psychosis exists, in which there is a delusive tendency, if not really existing delusions of grandeur, combined with a moral perversion, which brings with it a limited responsibility.

Richard Murphy, a little boy of eleven, registered at the Waldorf-Astoria hotel during the month of June, 1901. He was very small, very self-possessed and resourceful, and after assuring the manager of his solvency by a fraud, boldly made the acquaintance of several of the well-known habitués of the place, among them, Mr. Keene, Senator Depew, and other capitalists and politicians, with whom he talked much as an intelligent and well-informed man would, even criticising Mr. Keene's financial methods. He afterward fell into the hands of the reporters, who lost no opportunity of publishing his exploits. While his precocity was unusual and he possessed information of the topics of the day far beyond other boys of his age, not to say many intelligent adults, he was boastful to an extent that suggested that the things he stated were pathological lies if not delusions. He was on his way on a trip around the world, according to his statement, and at his home, in a small town in Missouri, was the editor of a newspaper of great importance and large circulation, and the number of his employees was very great. In the midst of his brief good time at the Waldorf, it was found that he was without means, and that he had resorted to the common trick of showing a dummy roll of bills which he had cleverly contrived. He was taken under the wing of a well-known Catholic priest, and his offences condoned by the hotel proprietor. During the two or three weeks he was at St. Vincent Hospital in this city, I examined him before he was sent home to his father in the West, who was, naturally, very much concerned about the escapade of his son. I found him to be a tiny boy, 4 ft. 5 in. high, with a dolicocephalic head. He had a deformed or V-shaped palate, but no dental irregularities or defects, His right palpebral opening was slightly smaller than the left, and there was a difference of over an inch in the length of the arms. There were no other defects indicative of imperfect development, and no actual abnormalities of the ears; his cutaneous surface was hyperæsthetic, and he admitted that he had habitually masturbated. In the presence of his friend, the priest, I talked with him for nearly an hour. He betrayed little or no acute moral sensibility, and would not explain his actions. He had theoretical views of an ethical standard, but these were elastic. There was a decided indication of the sincerity in the boy's manner and method of answering my questions, and that he was an enthusiastic believer in his own importance, and told wonderful stories of his newspaper I had no doubt, and this really amounted to exaltation.

When interrogated as to his newspaper venture he said:

Q.—When was it that you started that big paper?
A.—When I was eleven years old.
Q.—How large was it?
A.—It was sixteen pages, five columns wide and fourteen inches long.
Q.—How many subscribers did you have?
A.—We had 152 when we started; when I left home we had 14,000, distributed mostly in Jefferson City, St. Louis, and Chicago.
Q.—What is the size of Jefferson City?
A.—It has a population of about 20,000.
Q.—How many subscribers did you have in New York.?
A.—About 126.
Q.—I thought you had more than that in New York City.
A.—No.
Q.—What is the name of this paper?
A.—We kept the name of *Spectator*.
Q.—What are the profits?
A.—(To Father Ducey)—Do I have to tell this?
Q.—(Father Ducey)—It is for your benefit, you know.
A.—Well, you see I made clear—I charge a good deal for advertising, you know, and besides, we bought a good many things. I bought things during the year, you know. Now you mean what did I make?
Q.—What were your gross receipts?
A.—Well, about $12,000.
Q.—And your net receipts?
A.—About $7,000.
Q.—What did you buy? Presses?
A.—Yes, one Campbell's and two Chambers' and—
Q.—Did you have a Hoe press?
A.—We had already printed for some time on a Hoe, but only when we got out an extra edition.
Q.—What did the presses cost?
A.—The Chambers and—was $750 and the Campbell's $1,250. The office is on Madison between High and Main.
Q.—Some ill-disposed people said you did not have any office at all, that it is the place where your father is employed. Was that so?
A.—(Looking puzzled) I do not understand.
Q.—You have your own presses and plant, have you?
A.—I have my own plant. You just go into the *Tribune* office and see if it is not so.
Q.—You are taking a long trip, aren't you?
A.—Yes, it is a long distance.
Q.—Have you ever taken so long a trip before?
A.—Only little business trips for the paper, never so long as this before.
Q.—Have you been a great reader of newspapers?
A.—Well, we have a great many exchanges and I read them.
Q.—How tall are you?
A.—Three feet. I see (to stenographer, while measurements of his head are being taken) you write shorthand.
Q.—Did you have any stenographers in your office?
A.—Well, I should say! You ought to see my private secretary, he was a dandy!
Q.—How much did you pay him?
A.—Twenty-five dollars at the last. I paid him only fifteen to begin with.
Q.—What was your total weekly payroll?
A.—Two hundred and twelve dollars.

Nearly two years after his return home, he again appeared in New York and called upon me. I then questioned him about his previous experience, and he admitted that there "must have been something the matter with him" to have caused him to behave as he did at the Waldorf, yet he reiterated his stories of the important things he had done, and his possessions, supplementing them with others equally grand as to his career since. When he left me it was to call upon Senator Depew. He stated that he was without money which, at the time, I believed to have been the case. On the 26th of January, 1903, the newspapers were again filled with the exploits of young Murphy, who was arrested in Washington, after driving to several of the leading hotels in the endeavor to secure a suite of rooms with a private bath. When he was finally accommodated at the Raleigh, he dismissed the cab, giving the driver four times his usual fare. He was arrested for passing a worthless check for $20 in a New York department store on Sixth Avenue, and admitted that he had made a deposit of $5 in a savings bank, had obtained the pass-book, in which he had made false entries of deposits of $20 and $40. It was after this that he called upon the head of the dry-goods firm, who was a stranger to him, and by his assurance and apparent frankness, had induced that gentleman to certify his check for $20. This seems to have been but one of his many offences, and, in his portmanteau, it is said, were found playing cards, poker chips, and receipted bills of the best hotels throughout the country. It would appear that the boy's life, during the past year, at least, had been marked by consistent swindling, of the most ingenious kind. When arraigned before Judge Wyatt, he strenuously objected to having his case tried and wished to have it transferred to "a grown-up court.' His request was, however, denied, and he was sentenced to the Catholic Protectory on the 30th of January, where he now is.

Although various opinions have been expressed as regards this boy's condition and the manner of his responsibility, I am inclined to look upon the case as one of degenerative insanity, in which delusions of grandeur existed, in connection with very great

sharpness of certain faculties, and the blunting of the moral sense. It certainly is not simple precocity, whatever that may mean. I learn that there is a probable hereditary basis, and that the child has always been neurotic. From my several interviews, I am sure the boy believed the lies he told—certainly, his whole behavior supplemented this conclusion, and he was more than a mere criminal. Legally, perhaps, he was responsible, for his method of stealing had all the marks of cunning and acuteness. He surely had a comprehension of abstract right and wrong, and the knowledge of the consequences of his act, but he swindled that he might be able to live up to his expensive delusions.

The same morbid mental erethism is sometimes shown in other directions, and I can recall the case of a mere boy, of neurotic temperament, the son of a livery-stable keeper in a small country town, whose ideas of New York society had been imbibed from one of the yellowest of the Metropolitan papers. One of his first purchases when he came here was a suit of evening clothes, with which he hoped to gain admission to the much-advertised inner circles about which he had read so much in his favorite journal. His social ambition being thwarted, he became despondent, and finally dressed himself up, put a white flower in his button-hole, and then went up to Central Park, where he committed suicide.

The unstable condition which is found in these cases often leads to alcoholism and sexual excesses, even in boys and girls before puberty. Rossi and others publish numerous cases of alcoholism in children of tender years, two of these being in boys under five, and examples are more common in older subjects. I may, in this connection, refer to the personal case of a boy of ten years who had always been queer and different from others. He had a most fantastic imagination, and some ability as a draughtsman, at the age of five or six drawing constantly. His subjects were always allied to the horrible—devils, imps, and killing. He indulged in reckless and useless lying, read sensational stories, stole money frequently from the older members of his family, and took the silver brushes from his mother's bureau, which he pawned. This boy masturbated freely, and polluted the little boys who played with him. Upon one occasion, several years before I saw him, he was allowed to drink wine at the table. This seemed to stir an irresistible appetite, and upon another occasion he was found drunk from whiskey he had taken. After this it required the greatest care to keep him from taking spirits, but in spite of all that could be done, he was brought home unconscious upon several occasions.

The Goncourt brothers in one of their least known stories picture the degenerate daughter of a "camp-wren" or straggling army prostitute. This child, whose life is drawn with so strong a hand, manifested gradual insane upheaval of morals when her psychopathic state was intensified at puberty by compulsory sexual stress and excitement. The ultimate results were factious insanity of an incurable kind and dementia. It so often occurs that even when there is no expression of crime, a condition of elation and light mania may pass into one of the stuporous psychoses with ultimate dementia if strenuous measures of correction are resorted to. A case of this kind, in which insanity was evidently the amplification of an *originare verrüktheit*, was that of Czolgosz who, after his semi-maniacal outburst which led him to assail Mr. McKinley, was treated in prison with the most brutal violence for the purpose of extorting a confession and revealing the names of his possible confederates. When he was brought to trial there was a condition of mental torture and dulness as a reaction state that closely approached dementia. I was a witness of his manner in the court room, and feel sure he did not know the nature of the indictment to which he was asked to plead. These cases are referred to for the purpose of illustrating the susceptibility of some fundamental states of mental instability and weakness, to strain and pressure. They suggest the importance as well of humane and methodical management, care, and protection, rather than unreasoning harshness.

The management of vicious and insane children is full of difficulties, for on one side the unwise interference of the injudicious humanitarian does great harm, while on the other, the unthinking disciplinarian, who is loth to admit the irresponsibility due to disease, would have us treat them as other criminals. An example of the lax methods of the former and the serious consequences, allusion may be made to the case of A. Stewart, a boy who at the age of nine was committed in New York for truancy, but was released through the interference of friends. On March 31, 1897, he associated with young thieves and was again arrested and released. On October 21, 1897, he was arrested for vagrancy, and again on the 28th for truancy. On this occasion he was held for two months, when he was released. He was rearrested on March 28, 1898, and on March 22, 1899, on April 27, 1899, May 9, 1899, and finally sent to the House of Refuge, where he cut another boy's throat because, as he said, he "had a grudge against him." Although I understand this boy was found to be sane, there is a grave doubt as to whether he fully knew the nature of his act, and it is quiet probable that had he been continuously confined and subjected to intelligent discipline, he would never have committed the shocking murder.

So often is childish weakness that is not insanity regarded as responsible criminality that the children who might be guided aright by wise control are placed in penal institutions or sent to idiot asylums if they become incorrigible, or even trying. An occasional good school, presided over by a sensible man, or a training ship, of course, provided for a few, but what are really needed are correctional institutions where children are not stamped as young felons; farms and trades' schools and removal from malodorous tenements and association with older criminals. The governmental regulation of newspapers and injurious publications is to be hoped for, and the provision of a censor, as in Great Britain, who does some good in the regulation of plays, is perhaps a possibility of the future, while the enforcement of existing laws for the protection of minors would not only go far to suppress juvenile crime, but would diminish the force of many factors that now develop dangerous insanity in psychopathic subjects.

Separation of the Urine from the Two Kidneys.—Georges Luys discusses this question from the various points of view, dwelling with considerable detail upon the history of the development of the method. He claims to have been the first to practise the procedure in France, giving credit for the originality of the suggestion to Lambotte of Brussels, whose initial work on the cadaver and later upon the living subject was begun in 1890. In the same year Luys took up the matter, and by a careful presentation of the bibliography demonstrates the validity of his claim to priority. The clinical side of the subject is fully exploited, and the paper contains several illustrations of apparatus used and the proper position of patients for its successful employment.—*Revue de Gynecologie et de Chirurgie Abdominale.*

GASTRIC AND INTESTINAL CRISES.

By C. A. EWALD, M.D.,
BERLIN, GERMANY.
PROFESSOR AT THE KGL. FRIEDRICH-WILHELMS-UNIVERSITÄT.

I HAVE selected "gastric and intestinal crises" as the subject for my paper, because we deal here with conditions on the borderline between the specialty of stomach and intestinal diseases and other pathological states.

The "crises gastriques" are, for instance, only in a very small degree, if at all, the expression of a disease of the stomach itself, and must be considered rather as symptoms or reflex signs of other organic troubles.

Gastric crises, have, indeed, been first described in 1856 by Sir William Gull,[1] an internal clinician. The subject, however, was held in such small esteem, or rather excited so little interest, that Leyden, in 1863, in his work on diseases of the nerves, mentions only three cases, one of his own and two by other observers. It was Charcot and his school who were the first to recognize the im portance of this condition. Since the first reports from the Salpétrière, in 1868, many more cases have been reported.

It might, therefore, appear superfluous to revert to this theme. But since the clinical picture is not quite as well known as might be desirable, and since I have had the opportunity to observe an exceptionally large number of cases during a period of years, I hope to arouse your interest.

I will confine myself to those crises or attacks of colic originating from a distinct lesion of the central nervous system or from functional disturbances of the same, leaving aside any of the others that may be caused by kidney stones or gallstones, movable kidney or liver, by intoxications, worms, uterine or ovarian troubles.

By far the most interesting of these conditions are those crises arising in the course of sclerosis of the posterior columns of the spinal cord, typical dorsal tabes. And here those attacks are of most interest which are present in the very first stages of the spinal-cord affection at a time when the real classical symptoms of tabes are not yet present, and only some of the so-called preataxic symptoms, that are of rather dubious value and are easily overlooked, are found.

I wish to start out by saying that the early symptoms of tabese, ither singly or in greater number, could be demonstrated in all cases observed by me. Among these symptoms are:

1. Eye symptoms, *i. e.* reflex rigidity of the pupils, paralysis of the external eye-muscles and optic atrophy. I put less stress upon the inequality of the pupils, as this sign may frequently be present from other causes and even in perfectly healthy people. Lately O. Schaumann[3] has called attention to the fact that for special diagnosis differences in the pupils are of very little value. L. Mann[4] thinks that rigidity of the pupils is a more constant sign than the absence of the pastellar reflex; but we must bear in mind that it is a sign that may also occur in multiple sclerosis, cerebral syphilis, progressive paralysis, brain tumors, and even alcoholic neuritis (Gudden). Any single one of the signs just mentioned or about to be mentioned are not sufficient for a diagnosis; we must have at least two objective signs of tabes. The same, also, holds in regard to the reflex of convergence and myosis. We must also remember that the paralysis of the external eye-muscles which affect sometimes one, sometimes several muscles, are often evanescent in the first stage of the disease. Atrophy of the optic nerve occurs in only about 15 per cent. of the cases of tabes, according to statistics of Uthoff. This sign is said to occur often at a time when the patient is absolutely unaware of any other symptom.

2. Westphal's sign is of great significance, although it may occur outside of tabes. In one remarkable case I have seen it disappear and reappear at a later period of the disease.

3. Disturbances of sensibility are mostly present in the lower extremities—at times also in the trunk. Paræsthesia of the posterior pharyngeal wall and of the anal mucous membrane may occasionally appear as the first symptom of disturbed sensibility.

Feeling of abdominal constriction, disturbances of coördination, and lancinating pains are usually absent at this period.

Of the so-called gastric crises of tabes dorsalis, I have observed during the last ten years: In the hospital, 40 cases (54 attacks); in the polyclinic, 34 cases; in private practice, 15 cases. Total, 89 cases.

Unfortunately, I do not possess complete notes on all the cases, being only able to analyze fifty of them.

I assume that the general character of these attacks is known and will therefore at once proceed with my own experience.

The first question that occurs to us is, how frequently a syphilitic infection has preceded? In 26 cases syphilis was admitted 16 times, denied 7 times, and dubious 3 times. In nearly 62 per cent., therefore, a history of syphilis is present. This corresponds to the present view regarding the relation of both diseases.

The duration of the disease varies greatly. Among my cases are some of 10 years' duration. The average is about 2 years and 10 months. The shortest time was two months.

The attacks return always at shorter intervals. At first 1½ years may intervene, later only one year, ½ year, 3 months, 6 weeks, even 14 days; in the end they may appear every few days. In the same way the duration of each attack may vary. The attack may last from half an hour to 24 or 48 hours, and may at times consist in repeated attacks, so that the entire crisis may be prolonged for 2 or 3 weeks.

The course of each attack also varies.

Usually it begins with cramps in the epigastrium and over the cardiac area, accompanied first by slight nausea, followed later by vomiting. The latter is usually very intense and attended by violent pains. At first food remnants are vomited, soon, however, only mucus and bile, occasionally mixed with small amounts of blood extravasated from the capillaries. Real vomiting of blood is rare. It was designated by Charcot as black vomit. I have seen it only four times, combined twice with melæna.

In some of my cases the patients maintained that they were vomiting more than they had taken. Usually the attack comes as sudden as lightning, only to disappear as quickly, so that a person that has turned with pain only a few moments previously sits up in bed a few minutes later perfectly well enjoying his meal. In other rarer cases the attack begins slowly and gradually with a feeling of nausea and eructation on an empty stomach, becoming more and more intense and slowly disappearing again. I have also observed a sort of aura, consisting of pains in back or chest, feeling of constriction and depression.

Whereas we usually encounter violent, nearly unbearable, pains, these were entirely absent in two cases, and the attack was accompanied each time only by vertigo and vomiting. In one case stupor resembling deep coma resulted. Here there was

also present a pronounced gastrectasia, which also gave the symptoms of this trouble during the intervals between the attacks.

The character of the attack may frequently change in the same patient, gradually becoming less severe, so that eventually it consists only in a slight feeling of soreness and nausea.

It is surprising for how long a time these crises may precede the occurrence of severe tabetic symptoms. I have myself observed a patient for five years, during which time he had five attacks; in another the gastric crises covered a period of ten years. These are the cases in which tabes develops very slowly and insidiously. Usually the attacks abate in severity or stop entirely with the development of typical tabetic symptoms. I have, however, observed cases in which the crises lasted with increasing severity up to the stage of ataxia and the other grave complications.

As to the condition of the stomach in these crises it is evident from what has been said that a serious or lasting functional or anatomical disturbance cannot be present in most cases. We have to deal mostly, and if there are no complications, only with passing disturbances, referring to gastric secretion.

At first an increase of secretion, especially of HCl was assumed to be present. This, however, is surely incorrect. Among 37 cases in which the HCl secretion was determined, hyperacidity was found in 9 cases, normal acidity in 9 cases, and subacidity in 19 cases. The cases of subacidity largely prevail therefore over those of hyperacidity, and it has further been shown that during the attack, with the exception of one case in which an acidity of 25 was always found, the acidity is less than in the interval. Thus in one case during the attack no HCl was present, although ordinarily an acidity of 45 to 65 was found. The acidity of the vomited matter was regularly less than that of a test-meal given immediately before an attack. One case is on record in which the test-meal showed an acidity of 46, the vomit of 40, and the empty stomach of 50, speaking for the presence of parasecretion.

The condition of the patients in the interval is usually good as far as the stomach is concerned. There are, however, some cases in which dyspeptic disturbances are present at all times.

The bowels were usually sluggish, and in only two cases was there diarrhœa during and after the attack. The urine shows no special changes, the occurrence of traces of albumin and occasionally of acetone not being characteristic of the attack.

Much less frequent than the gastric crises are the intestinal and especially the anal crises.

The first are characterized by cramp-like contractions of the abdomen, especially the hypogastrium, accompanied by intense boring or tearing pains. The abdomen is hard as a board, sometimes of a scaphoid shape. In some parts, for instance in the ileocæcal region or over the pubes, protuberances of the size of a walnut to that of a fist, may occur and disappear again with a gurgling sound. There is a desire for stool with a high degree of constipation, and the inability to expel wind. The attack usually lasts only a few minutes but recurs several times during the day and then disappears. Such attacks return at stated periods, in the meantime the abdomen being perfectly normal.

The rectal crises are especially characteristic. The patients suffer from a strong desire for stool, but without result. Only a few small fecal particles and mucus are discharged with a great deal of effort. The patients experience the sensation as though a sharp knife or a hot iron was being turned around in their rectum. These attacks are exquisitely painful, but disappear quickly, and the patient then feels as well as before.

The diagnosis of gastric crises is difficult because they occur mostly in the so-called preataxic stage of the disease, *i. e.* at a time when specific symptoms, as disturbances of coördination, marked disturbances of sensibility, affection of the joints, etc., are still absent. I have already spoken of the significance of the various signs.

I attach the most importance to the mode of development of the attacks, occurring at first rarely, later more frequently, the previous history of syphilis and, as far as the character of the attack itself is concerned, its frequent beginning with cramp-like boring and tearing pains in the epigastrium, which later are accompanied by vomiting. As far as this last symptom is concerned, there may be various modifications and deviations from the regular course, as explained above. Vomiting or pain may be absent, just as the character of the attacks may vary in one and the same case.

It is difficult to separate the real tabetic crises from the attacks of nervous vomiting, as may occur sometimes with organic, usually functional, disturbances of the nervous system. Charcot observed periodic vomiting in general spinal paralysis, in multiple disseminated sclerosis, and in compression of the spinal cord in its cervical portion by a fractured vertebra.

Similar observations have been recorded by later authors. These cases offer, however, no special difficulty, according to my experience. These attacks usually lack the distinctive type and occur, as a rule, only when the symptoms of the original malady are already well advanced, whereas the characteristic sign of the gastric crises consists in the absence, or at least the insignificance, of the specific symptoms of tabes.

It is much more difficult to distinguish them from those attacks of nervous vomiting recurring periodically without demonstrable disease of the central nervous system, such as has been described in Germany, especially by Leyden[5] and Boas, and which has been named paroxysmal or idiopathic vomiting.

These attacks very strongly resemble tabetic crises. They differ, however, in the following points:

1. There is nothing typical about the time of the attacks, or they may present a peculiar type of their own, the attacks recurring, not at successively shorter intervals, but rarely, and then always with regularity. Thus I have observed in young girls stomach cramps regularly, or with longer intermissions at the time of menstruation, accompanied by vomiting or nausea. They looked pale and anæmic, had no appetite, a coated tongue, etc. In other cases the crises recurred at a certain season —for instance, the spring or the fall.

2. There are no specific signs present pointing to a disease of the spinal cord.

3. Neurasthenic or hysterical symptoms are usually present.

4. Such attacks are usually brought on by the partaking of food, and it frequently may happen that the same article of diet may precipitate an attack at one time and not at another.

5. *Exjuvantibus*, it may be said that the so-called idiopathic crises may be influenced therapeutically, which is hardly ever the case with the true tabetic crises.

Other kinds of crises that might be considered are the painful vomiting of lead colic, of severe morphinism, of pregnancy, or accompanying the formation of stones in the gall-bladder, kidney or bladder,

also the vomiting of grave malaria, and reflexly from the uterus or bowel and intestinal parasites.

All these conditions may be diagnosed by a careful examination—sometimes, of course, only after a longer period of observation. Errors, however, cannot always be avoided. A case has been published from Leyden's clinic in which gastric crises followed a lead colic, and the true nature of these attacks was discovered only after a long period of observation. I, myself, have diagnosed "crises gastriques" of tabes in a patient upon whom later a surgeon, under the assumption of the presence of gallstones, operated unsuccessfully.

A case detailed by Werner[6] is, perhaps, most characteristic in this respect. It concerns a woman who, since 1883, complained of gastric pains, which gradually developed into true gastric crises. At first they were attributed to the pregnancy of the patient and were treated by cauterization and dilatation of the cervix. Since they remained after confinement, and symptoms of dilatation of the stomach developed, a gastric ulcer with pylorospasm was diagnosed, and on May 4, 1887, a gastroenterostomy was done by Hahn of Berlin. After the operation, the crises continued unabated, and they were now attributed to the adnexa of the uterus, and the patient was, accordingly, castrated on November 4, 1887. This operation was also unsuccessful, the patient vomiting until February, 1888. At that time the vomiting stopped and she was free from all troubles. Now all signs of tabes developed, together with those of phthisis, of which she died on June 5, 1888. The autopsy revealed a marked sclerosis of the posterior horns and phthisis. The gastric intestinal fistula was also found, and at its opening in the stomach an ulcer had developed, as sometimes happens after these operations.

From such cases we learn to what errors a wrong diagnosis of these crises may lead and how important a correct appreciation of the condition of the patient may become.

The same may be said of intestinal and anal crises, these varieties being, however, much less frequent than the gastric crises. The diagnosis in these cases, however, is, in my opinion, somewhat easier, as the symptoms of tabes are usually well marked at the time of their occurrence, so that a little doubt as to the nature of the attacks exists, as in the laryngeal crises, the lancinating pains in the joints, feeling of constriction, and other conditions of the sensory or sensory motor sphere.

As to the true nature of these crises, we are still absolutely in the dark. We know that their origin must be central, whence radiates a periodical stimulus to the periphery. At various times during the course of years nuclear lesions or neuritic changes have been observed by different investigators in the roots and peripheral nerves, especially the recurrent and sympathetic nerves. Kahler, Demange, Landouzy, Déjérine, J. Ross, Oppenheim, and others have found these changes. Other lesions that have been noted are atrophy of the root of the vagus, pigment atrophy, and degeneration of the sympathetic ganglion cells and of Remak's fibers, degeneration of the peripheral vagus, and of the laryngeal nerves, etc.

All these lesions, however, were found after the disease had reached its climax and was over the crisis. Neither do they explain the periodicity of the attacks, which can hardly be reconciled with the presence of a lasting histological change. Some special stimulus must without doubt be present, just as in an epileptic seizure. As to their nature, we are unable to say anything. To me it appears most likely to be a sort of autointoxication, characterized by the presence of a toxin or chemical substance which has no influence upon normal nerves, but readily produces a state of irritation on such nerves whose neuronic integrity has been impaired. Thus the frequency of the attacks increases as the degeneration of the nerve elements progresses. That each single attack reaches a climax, thereby exhausting itself, is also not without analogy. Finally the attacks cease because the line of transmission has been destroyed or, at least, does not respond to the stimuli sent out.

Regarding the treatment of the crises dependent upon a disease of the central nervous system, nothing very favorable can be said. I have used at various times the most varied means to suppress the attack as such in a symptomatic manner, or which, by attacking the original disease, were to prevent the recurrence of the attacks (suspension, antisyphilitic treatment, silver nitrate, etc.).

First of all, I must emphasize the fact that we do not know of any means of cutting the attack short. It has been said of some of the antinervines, *i. e.* antipyrin, strychnine ($\frac{1}{30}$ grain subcutaneously), cerium oxalate, that they occasionally shorten and alleviate the attack (Ostankoff, Basch, Oppenheim). Thus Basch[7], among 18 cases, saw the attack cut short twice and alleviated three times after the use of 1½ grains of cerium oxalate every 3 hours, as soon as possible after the beginning of the attack. I have used this drug only in few cases, as it was always entirely without effect even in 2½-grain doses.

The occasional success of this and numerous other drugs that have been recommended from time to time (*e. g.* amyl nitrite, or erythrotetra nitrate [Pal]) is difficult to estimate properly, because the attacks vary so much in their course and severity, and because tabes, as is well known on account of its proteus-like nature as a disease, easily influenced by suggestion. It is a well-known fact that each new method of treatment of this disease is at first ushered in by an ephemeral success.

In grave cases we must have recourse to morphine, and we will usually, in the beginning, be able to check the attack with relatively low doses. The amount of morphine, however, will have to be increased, the more frequently the attacks return and the quicker they succeed one another. I have had several patients in whom large doses of $\frac{1}{3}$ or $\frac{1}{2}$ grain of morphine, given repeatedly during the day, produced only an alleviation but not a cessation of the attack.

There is a further danger in the fact that these patients readily become morphinomaniacs and eventually take a subcutaneous injection whenever they feel the least discomfort in the epigastrium.

Just as in all other colics that return periodically, as gallstone or kidney colic, the individual behavior of every patient toward morphine is different. Some resist a long time, others easily get rid again of the habit, and the third class fall victims to the morphine habit. I never allow the patient to use the syringe himself, no matter to which category he belongs. It would, however, be absolutely wrong to withhold morphine for fear of forming a habit. As I have previously[8] shown in these cases, it does not shorten life, but rather prolongs it.

As the nerve irritant probably is sent out from the central nervous system by way of the posterior horns, success would seem to be promised by means of a method of treatment, which was described years ago by Leonard Corning, but which has only recently been extensively tried by a French physician, Fernand Chatelin. This method consists in the injection of local anæsthetics into the epidural space of the spinal cord from the sacrum. For this

purpose we look for the two small bony prominences which constitute the fifth posterior and inferior sacral processes and which are situated on both sides of the termination of the rima ani. Here a small triangular depression is perceptible, into which the cannula is thrust. Such injections have, indeed, been employed by Hulier and Vidal in one case of gastric crises due to ulcer of stomach, by Berguignan in the vesical crises of a tabetic patient. The solution employed in such cases is made up of sodium chloride, 3½ grains, cocaine hydrochlor. 1½ grains, and sterilized water up to 3⅔ ounces.

I myself have used these epidural injections in a number of cases, and can assert that technically the procedure is simple and easy. With none of the patients were there any special painful sensations, paræthesias, or pareses after the injection.

The treatment of cases of periodic vomiting due to functional neuroses, *i. e.* idiopathic vomiting, is much more satisfactory than that of gastric and other crises due to organic changes in the central nervous system. General tonic treatment by means of hygienic and dietetic measures and suitable drugs (iron, arsenic, etc.) will accomplish a great deal. Locally, irrigation of the stomach with soothing or slightly astringent solutions (aq. chlorof., argent. nitric.), sedatives (especially bromides, hyoscyamus, orthoform, etc.), and, if vomiting is of reflex origin, painting the nasal mucous membrane with cocaine are usually of value. We cannot, however, deny that obstinate cases may occur, which defy treatment for a long time and which lead to great weakness of the patients. Here the differential diagnosis will be especially difficult, so that often extended observation or the course of the disease can decide the question.

Middle-ear Disease in Tuberculosis.—The views of Robert Levy are summarized in the following statements: (1) Any of the usual aural affections may affect the tuberculous as well as the non-tuberculous. (2) The usual modification of an acute otitis in a tuberculous subject is manifested in the course the disease pursues. (3) It is a doubtful question whether the bacillus tuberculosis is present as a distinctly etiological factor or as an accident. (4) Comparatively few cases of tuberculosis in children and relatively few instances of bone tuberculosis are met with in Colorado. (5) Clinical tuberculous otitis occurs with moderate frequency in Colorado, being secondary to lesions of the respiratory torgans. (6) Tuberculous otitis may develop when the general symptoms of tuberculosis have been arrested and the patient's condition unusually good. (7) Tubercle bacilli may find their way into the middle ear through the Eustachian tube, through the lymph channels or the blood currents. (8) Unusual care must be exercised in the application of the nasal douche in tuberculous patients. (9) The discharge may be arrested, but not permanently as a rule. (10) It must be exceedingly rare for miliary tuberculosis to develop from an otitis as the focus of infection. (11) Through-and-through irrigation with tubercle-bacilli-destroying agents is of prime importance in the treatment. (12) General and climatic treatment must be conscientiously carried out.—*The Laryngoscope.*

INTRAVENOUS INFUSION IN PUERPERAL SEPTICÆMIA.

By EDWARD WAITZFELDER, M.D.,
NEW YORK.
CONSULTING PHYSICIAN RANDALL'S ISLAND HOSPITALS; VISITING PHYSICIAN GOUVERNEUR HOSPITAL.

The following cases were treated at Gouverneur Hospital during my recent term of service. Although but two cases are reported, the results, particularly in case II, are sufficiently suggestive to warrant their publication, with the hope of a further trial of the treatment in puerperal septicæmia.

Case I.—M. B., aged twenty-six years, primipara. Admitted to hospital December 28, with the following history: About three weeks before, the patient had a normal labor. After two or three days she began to complain of fever and occasional chilliness, loss of appetite, sweatings, etc. These symptoms increased in severity until she was compelled to come to the hospital. On admission her symptoms were as above; the cervix was large, dilated and boggy, and the seat of a bilateral laceration. The uterus was enlarged and but slightly tender on pressure. Temperature, 100½°; respiration, 40; pulse, 116.

On the following day the temperature rose to 103°, and on the next day (third in hospital) to 105½°. The patient was curetted and a large mass of post-partum detritus and blood-clots was removed; uterus irrigated with an antiseptic solution and a gauze drain was introduced; this was removed after thirty-six hours.

The following day the temperature fell to 101°, but only to rise to 104° within the next twenty-four hours.

On January 2, when I first saw the patient, her condition was as follows: She was in a semi-apathetic condition, temperature, 104¼°; pulse, 118; respiration, 28; abdomen slightly distended and tender over the uterine and left hypogastric regions. Examination of heart, lungs, and kidneys gave negative results. There was no change during the next five days, the temperature ranging from 101° to 104½°; the pulse was always between 108 and 130, the patient gradually growing weaker and losing ground.

On January 7 I removed the entire endometrium with a sharp curette and applied pure carbolic acid to the denuded surface; this was done to remove the local foci of infection, disinfect the uterine cavity and seal up the opened lymph channels. It was followed by a fall of temperature to 100°.

The next day (eleventh in hospital) the temperature again rose to 104°, and on the following day to 104½°; the next day (January 9) to 105½°. At this time the patient's condition was so bad, the pulse so weak, and her vitality so low, that she was given a hypodermoclysis of 750 c.c. of decinormal saline solution. This was given only with the idea of keeping the patient alive during the night. It was followed by a chill lasting half an hour and a rapidly falling temperature, so that, twelve hours later, the thermometer registered 96¼°; a fall of 9¼ degrees.

The following day (January 10) the temperature rose to 103¾°. January 11, temperature 105°; a hypodermoclysis of 750 c.c. decinormal saline solution was given, followed by fall of temperature within twelve hours to 102°. January 12, maximum temperature, 104½°.

January 13, maximum temperature, 105½°; hypodermoclysis of 1,000 c.c. decinormal saline solution. Temperature fell to 99¾° within twelve hours; but it rapidly went up again to 105¼°. At this time pneumonia developed in the left lung and consolidation was complete in twenty-four hours.

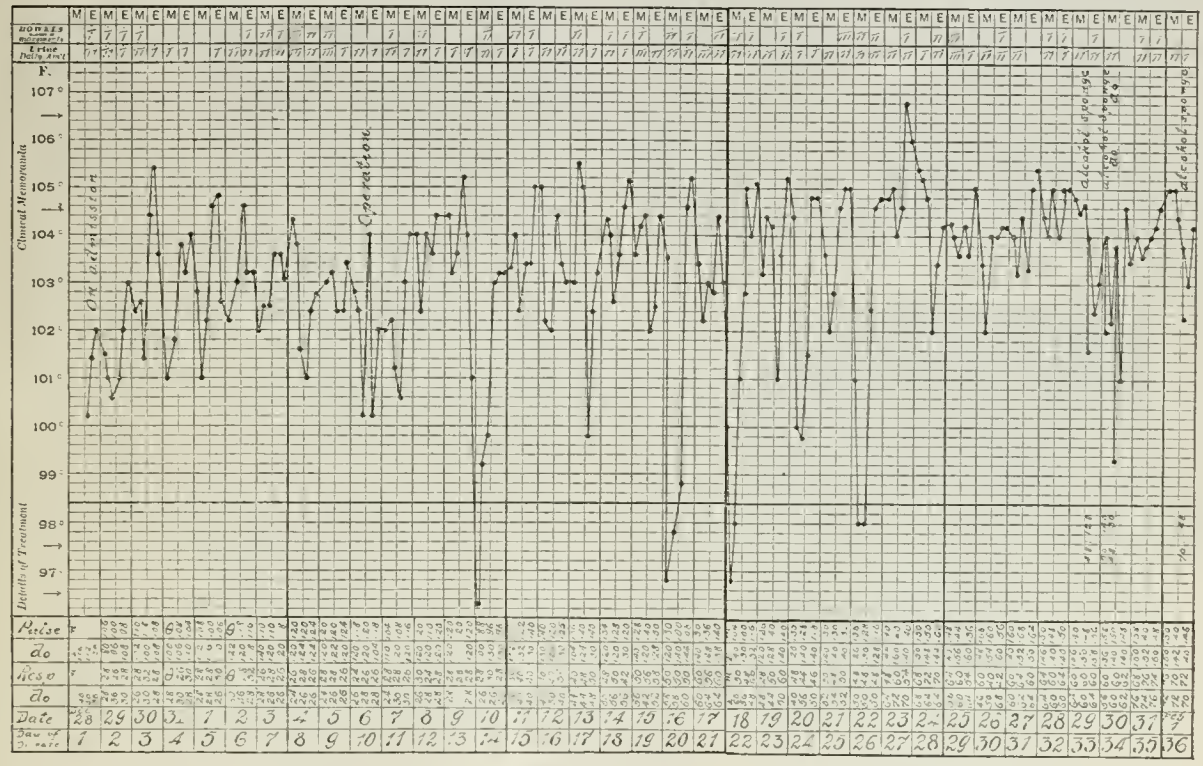
January 14, the patient's condition was appar-

ently hopeless; the septicæmia showed no signs of abating, respiration about sixty to the minute, labored and shallow; pulse very weak and at times irregular. At this time my attention was called to the treatment of puerperal septicæmia by the intravenous infusion of formalin solution, 1-5000, and I directed my house physician, Dr. Whitman, to give the patient 750 c.c. of this solution into the vein of the arm. This was done at 9 P.M., when the temperature was 104½°. It was followed by a chill lasting twenty minutes, and during the next twelve hours, the temperature fell to 96¾°, a fall of 7¼°. Within the next twelve hours the temperature rose to 105¼°, higher than it had been at the time of the formalin infusion. January 16, condition of patient unchanged. January 17, temperature, 104½. I determined to give the formalin infusion again. After 90, or at most 100, c.c. had passed into the vein, the patient stopped breathing, became pulseless, and I thought she was dead. Hypodermic injections of whiskey and strychnine and oxygen inhalations revived her, and discontinuing the formalin solution, 750 c.c. given, followed by fall of temperature to 99¾° within twelve hours. This infusion was not followed by a chill, but by a most profuse perspiration, which lasted throughout the entire time of falling temperature. Before this infusion was made a specimen of blood was again taken for examination. Professor Schultze subsequently reported the streptococci present, but in reduced numbers.

January 20, temperature, 105°; respiration, 56; pulse, 140. General condition of the patient very bad.

January 21, temperature, 105°. Intravenous infusion of 750 c.c. formalin solution was given, followed in one hour by a very profuse perspiration, and in twelve hours by a fall in temperature to 98°.

January 22, maximum temperature, 104¾°. The patient's condition was so bad and the heart's action so weak that I feared the removal of the patient to the operating room for intravenous infusion might be followed by a fatal result, so I directed a hypodermoclysis of 750 c.c. of decinormal saline solution.



CASE I.

tion (which I thought had been the cause of the collapse), I gave an intravenous infusion of about 900 c.c. of decinormal saline solution. This was followed in one hour by a chill lasting fifteen minutes.

Prior to the infusion, a specimen of blood was taken to be submitted to Prof. O. H. Schultze of Cornell University for examination. He subsequently reported the presence of streptococci in the blood.

Within twelve hours of the infusion of the decinormal saline solution (I exclude the formalin solution as entering into this infusion on account of the small quantity used) the temperature dropped to 96¾°, exactly where it had fallen after the formalin infusion. In fact, a comparison of the temperature chart after the normal saline solution and after the formalin solution infusions shows identically the same temperature changes, viz., a fall from 104½° to 96¾°.

January 18, temperature, 105°; respiration, 64°.

January 19, temperature 105¼°. Infusion of formalin solution, 750 c.c. This was without result on the temperature.

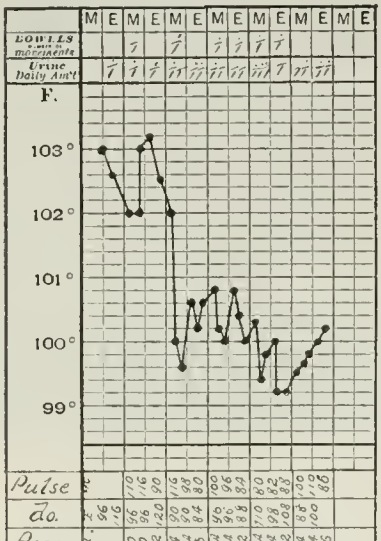
January 23, temperature, 106¾°; respiration, 70; pulse, 150. No sign of resolution in left lung; posterior (hypostatic) congestion at base of right lung.

Hypodermoclyses of decinormal saline solution, averaging from 750 c.c. to 900 c.c., were given on January 27, 28, 30, 31 and February 1. From January 23 the condition became worse and worse, the temperature never falling below 103¼°, and the respiration always remaining above fifty per minute until her death on February 2.

On February 1, about thirty-six hours before death, I obtained a specimen of her blood, which was said by Professor Schultze to be free from the streptococci. In the light of this report I am compelled to believe that the persistent high temperature of the latter part of this history was due to the pulmonary involvement and not in any way dependent on a condition of septicæmia. I have reported this case in detail because of the conclusions I draw from it and because of the bearing it had in determining my treatment of the case subsequently to be reported.

The patient came to the hospital with a well-marked puerperal septicæmia. After following the usual treatment in such cases for about two weeks, the condition going from bad to worse, I was compelled to look on the case as hopeless and death inevitable from septicæmia. At this time I used the formalin infusion after the plan of Dr. C. C. Barrows. I was impressed with the idea of directly introducing the germicide into the blood and thought we had at last discovered the way to remove systemic septicæmia. The result of the infusion was all that was looked for; but the improvement did not last, and after forty-eight hours, a second intravenous infusion was given, this time of decinormal saline solution; the result was identical in every way; the temperature curves being a repetition one of the other, the chills and sweating being exactly the same. I then began to think that perhaps the result was not due to the formalin but to the over-distension of the blood vessels with the resulting increased action of the skin and kidneys carrying out of the circulation an amount of septic serum equal to the amount of water infused. I was the more impressed with this idea in consequence of the marked fall of temperature on January 7, a fall of 9¼° following a hypodermoclysis of normal saline solution.

As I did not receive the bacteriological report of the blood specimen of January 19 in time, I gave another formalin infusion, the last, on January 21. All the subsequent infusions and subcutaneous injections during the period of eight days before the death of the patient were of decinormal saline solution.



CASE II.

The 750 c.c. of 1-5,000 solution used by Dr. Barrows, when mixed with the total volume of blood, becomes a solution of about 1-50,000 or 1-60,000, and a solution as weak as that probably inert.

I was therefore impressed with the idea that the result was due, not to the germicidal properties of the formalin, but to the transudation following the over-distension of the blood vessels, and determined to treat the next case of puerperal septicæmia with a large intravenous infusion of normal saline solution. This case presented itself on February 1 with the following history:

CASE II.—B. F., aged thirty years, married eleven years; six children; youngest two years of age. Eight days before admission patient aborted at about the third or fourth month of pregnancy, the entire contents of uterus being expelled. After three or four days she had a chill, followed by fever, sweating, etc.

On admission to the hospital the temperature was 103°; pulse, 96; respiration, 36. The uterus was slightly enlarged and softened; thick mucopurulent bloody discharge from cervix; feeling of discomfort, but no decided pain over the uterus.

When I saw the patient on the next day her condition was as above, but her temperature had risen to 103¼°. She received at once an intravenous infusion of 1,200 c.c. of decinormal saline solution at a temperature of 110°. This was followed in one hour by a chill lasting about twenty minutes and a fall of temperature (during twelve hours) to 99¾°. During the same time the pulse fell from 116 to 80 per minute, and the respirations fell from 30 to 18 per minute. Prior to the infusion a specimen of blood was taken and presented to Professor Schultze for examination. He reported the presence of streptococci.

For twelve hours after the infusion the temperature and pulse remained practically normal and the patient free from morbid symptoms of any kind until the time of her discharge from the hospital on the sixth day after admission. I did not wish the patient to leave so early, but she was resolute in her determination to go, so I was compelled to discharge her.

I desire to call special attention, in the history of Case I, to the temperature curves of January 15 and 16, and of January 17 and 18—these following on the former date a formalin infusion, and on the latter date a decinormal saline infusion, and also the temperature of January 9 and 10—this extreme fall following a subcutaneous injection of 750 c.c. of decinormal saline infusion.

209 WEST TWENTY-SECOND STREET.

THE CORRELATION OF ALCOHOLISM, CRIME, AND INSANITY.*

BY C. A. DREW,

MEDICAL DIRECTOR STATE ASYLUM FOR INSANE CRIMINALS, BRIDGEWATER, MASS.

ON December 21, 1901, J. M., a smooth-faced boy of seventeen years, of fair complexion, dark-brown hair and blue eyes, was admitted to the State Asylum for Insane Criminals from the State Reformatory. The physician's certificate upon which the commitment was based reads as follows: "To His Excellency W. Murray Crane: We have this day examined J. M., seventeen years of age, committed August 4, 1900, for larceny, sentence expires August 29, 1905, and would respectfully report: J. M. has been reported several times for being noisy at night; he has been five times reduced to the third grade. At one time he tried to escape and was found with a club, with which he was going to try to assault the officer. He was quite pleasant at our examination and announced at once that he was an anarchist; that he did not believe in society, but was a society man. That eminent men in the State appeared to him at night in the spirit form and threatened him with false charges, and it was not infrequent to have the spirits of some of the officers present at the same time; that he was going to kill all of them, as well as some people who were trying to cheat him out of a large farm in Texas that has been in his family for years. During the whole of the examination he would smile most of the

*Read before the American Association for the Study of Inebriety in Boston.

time, but sometimes he would scowl and try to appear very earnest. His pupils are dilating, his pulse is small and irregular, and he has lost fifteen pounds. There is much about him that is undoubtedly assumed, and nearly all the stories about his education and habits are false; he says he is a graduate of Harvard and was sentenced here for killing two Chinamen at Three Rivers, but he has been very persistent in his threats at killing, and he harps on the ghosts coming into his room at night and has lost flesh, although he eats his rations all up. We feel that he has delusions of persecution that are more or less mixed with weak-minded ideas of anarchism, and advise that he be sent to the asylum for insane criminals."

It is in the records that this young man was found on examination to have a fairly well-developed bony framework, but rather thin in flesh, cutaneous circulation sluggish, pulse small, regular and easily compressed, heart and lungs, palate and ears normal; tongue protruded straight with no marked tremor and no knee-jerk, the so-called "patella reflex." could be obtained.

Concerning the mental examination it is written that he was "moderately excited, silly, frequently making irrelevant remarks. Alternately scowling and grinning. Has considerable difficulty in collecting his thoughts, but memory appears good. Apparently has had delusions of various character for some time. Says that the officers made trouble for him and provoked him; that one of the officers beat him. Says he has been unable to sleep for some time; that he broke up the furniture. Says that he wanted to kill one of the officers there, and that when he gets a chance he will run a knife into him."

Concerning his previous history as related by himself. He says "he is twenty-one years old and thinks he was born in Worcester, Mass., but is not sure, as he was put into an orphan asylum when a baby. Father, Jeremiah, is dead. Mother, Ellen, married now to M. L. B. Thinks he has one sister dead. Family history unknown. Has been smoking, chewing, and drinking since eight or nine years of age. Drunk 'lots of times.' Has been through the grammar school. Sent to Oakdale Truant School at fourteen for two years. His first arrest was for stealing knives in Worcester; put on probation. Next for stealing rubbers. Probation. Next for stealing a copper boiler. Spent about two months in House of Correction, Worcester, then discharged. Next arrested for stealing silk skirts. Sent to Lyman School, assaulted an officer there with a base-ball bat and was transferred to Concord. While in the latter place has been frequently punished for breaking the rules, striking officers, and breaking furniture."

I read you the plain records of this case, because this young man represents a class, not small, numerically, among those admitted to the Massachusetts Asylum for Insane Criminals, and because his case embodies some facts and illustrates some truths related to the subject of this paper. There are phases of his case pointing to a bad heredity and certain symptoms doubtless depending on the direct toxic effect of alcohol on the cortical neurons of the cerebrum. An almost total absence of moral sense is not uncommon in patients whose father and mother were both inebriates, even though the patient has never used alcoholics. And we do occasionally receive a patient, born of inebriate parents, who is an abstainer from alcoholics, not for any moral reason, but seemingly because his embryo organism revolted from the alcohol in his mother's blood. Fantastic and irrational ideas, hardly fixed sufficiently to be called delusions, are common to the weak-minded offspring of such parents. It should be noted that our patient says he was put into an orphan asylum when a baby, and we have very little reliable information concerning his parents; but I would observe that it is not usual for a boy of eighteen or twenty-one, even, though he has been smoking, chewing, and drinking since the age of eight or nine years, to have progressed so far in crime, unless a neuropathic or alcoholic heredity was his heritage. His claim of being an anarchist, that he did not believe in society, etc., was doubtless the fruit of his reading about the assassination of our recently-deceased President. The loss of knee-jerk, or patella reflex, as well as other nervous symptoms present on his admission, suggested a condition approaching multiple neuritis, of which alcoholism is the most important causative factor. Ordinarily acute alcoholic insanity is curable, but moral imbecility or instinctive criminality, due to a neuropathic or inebriate heredity, is usually incurable, and I am not very hopeful concerning the future of our young friend, J. M.

I would add that J. M. is not demented in the ordinary sense. On the contrary, his mind is very active, and he looks you in the eye with a saucy, defiant smile. He is fertile in resources in attempting to change his dwelling-place. He has slid down a dust shoot from a second story, climbed the face of a brick building by the aid of projections which a good sailor might have hesitated to utilize, passed hand over hand along telephone wires toward what seemed to him to be liberty, until the wires broke, leaving him, after something of a fall, unharmed and still within a walled enclosure. Feigning a desire to have his window closed, he called a strong, experienced nurse into his room at night and attempted, by a sudden attack, to take the latter's keys, notwithstanding the nurse was forty pounds heavier and stronger than himself. Failing to get the keys, he sprang quickly from his room, turned a lock from without, leaving the nurse a prisoner within, while he waited in the hospital corridor for another nurse to capture, perhaps feeling as proud as did General Funston after the capture of Aguinaldo. The other nurse captured J. M., but our hero was not discouraged; it is not in his mentality to be discouraged by creatures of flesh and blood. He is a favorite among his fellows and is as devoid of fear as the dare-devil fictitious heroes of Anthony Hope or Richard Harding Davis. His social instincts are well developed, and let me say in passing that good men and women seem to be waking to the transcendent importance of the social instinct in the human animal. This seems to me to be among the most hopeful signs of the times, for the social instinct, of which the procreative and maternal instincts are parts, is a living power, ever acting, leading to an earthly heaven or hell, according to which way is made the most attractive.

Turning from the concrete case of J. M. to the more general question of the correlation of alcoholism, crime, and insanity, a time limit alone would exclude all but a few of the pertinent facts which have come under the writer's observation. During the year ending September 30, 1901, cases were admitted to the Prison Department of the State Farm as follows: 1,118 cases for "drunkenness," 311 cases as "vagrants" or "tramps," and 29 as "vagabonds" or for being "idle and disorderly," 18 cases were committed for other offences, the majority of whom were transferred from other penal institutions that the prisoner might have the benefit of the hospital department of the State Farm. Of this total of 1,476 cases admitted within

a year, 691 had been previously committed. For 356 this was the second commitment, for 10 it was the eighth commitment, and for 1 it was the seventeenth admission as a prisoner to the State Farm.

During the past two years 154 cases were committed to the State Asylum for Insane Criminals—an offspring and department of the State Farm—by due process of law. These 154 cases were from the various penal institutions as follows: 35 from State Prison, 35 from the several Houses of Correction in Massachusetts, 15 from the Massachusetts Reformatory, 10 directly from the courts or jails—not having received sentence—and 58 from the Prison Department of the State Farm. Twenty-three of these 154 cases were arrested for crimes "against the person" including 4 cases for assault with intent to kill, 2 cases for manslaughter, and 6 cases for murder. Breaking and entering was the charge in 24 of the 154 cases. It is difficult to get a reliable family history from many of these patients and almost impossible to get the truth from near relatives. These men usually talk frankly, sometimes boastfully, of their own shame. Many do not hesitate to tell the truth about a father's intemperate habits, but a mother's weakness is another question, and to lie boldly and perseveringly, lest a reflection be cast on her name, is an impulse native even to the typical insane criminal. But in spite of the difficulties, the painstaking efforts of my senior assistant has secured information in the majority of cases, in which such errors as exist will be in the minimizing of the facts pointing to a bad heredity.

Of the 154 cases admitted in two years, 11, or 7 per cent., claimed never to have used alcohol as a beverage. Of these 11 cases, 3 were epileptics and 2 were well-marked cases of imbecility. This will indicate how rare it is for one who is an abstainer from alcoholics, and not an imbecile or an epileptic, to be sent to the Asylum for Insane Criminals in this State. Ninety-six, or 62 per cent., of these cases considered themselves hard drinkers, the majority having been drunk many times. The remaining 31 per cent. considered themselves only moderate drinkers, or were too demented to tell, or for personal reasons refused to give information concerning their habits as to the use of alcoholics. Fifty-six, or 36 per cent., of these cases acknowledged intemperate fathers, while 21, or less than 14 per cent., acknowledged intemperate mothers. For many reasons it is impossible to say just what proportion of our patients are insane because of alcoholism, even more difficult than to determine just how much of the crime in our land is due to the same toxic agent. My observation leads to the belief that the offspring of sound, temperate parents are less likely to suffer from alcoholic insanity, though heavy drinkers, than the second generation who may not drink one-half so much. I would agree with Berkley* that "pronounced alcoholism in the parents always means examples of mental disease and weak-mindedness in the children, provided the alcoholic tendency is not acquired somewhat late in life." An inebriate father is certainly a handicap, an inebriate mother is a greater misfortune, but the offspring of an inebriate father and mother seems almost to be doomed from its birth. The question whether alcohol may be called a food—so much debated—seems to me to be mainly of academic interest, largely a splitting hairs over terms.

I prescribe alcohol sparingly as a medicine, as I I do strychnine, nitroglycerin, and digitalis, but almost never alcohol in case of young patients. But as a food, beef essence, cereals, and peptonized milk are much more reliable friends.

*Mental Diseases, page 106.

The pathology of alcoholism, criminality, and insanity each has a length and breadth of its own and can hardly be touched upon in this paper.

The man who drinks because his comrades drink is not of a kind with him who yields to an impulse from within which has almost the resistless force of an epileptic explosion. The latter is just as truly the victim of a neurosis as the epileptic. The instinctive criminal, the habitual criminal, the occasional criminal, and the criminal by passion are not of a kind, although the lines of demarkation cannot be sharply drawn. In all these cases, however, alcohol plays an important causative rôle, because, as Victor Horsley† of England Kraepelin‡ of Germany, Berkley§ of Johns Hopkins, and others have affirmed and demonstrated, the oft-repeated presence of even a moderate quantity of alcohol in the circulation will cause marked changes in the cortical neurons of the brain; a change in the shape of the nucleus, the disappearance of the granular masses, and the shrinking of the protoplasm of the cell body are among the changes discovered by modern laboratory research. Because these cells are the material basis of man's moral sense and conscience, the physical representatives of his aspirations, his likes, his dislikes, his hopes, his fears and his will power, their harm or immunity from harm seems to me a question before which the question of the food value of alcohol, or the effect of alcohol on stomach and liver, even is insignificant. It seems to be a law of nature that the most highly organized tissues suffer first and most from toxic agent in the blood, and so it is that the moral and ethical sense suffers first and most, and is often the only manifest evidence, in the first generation, of the baneful effects of alcoholics taken in moderate quantities, even as these attributes of mind are the latest developed and the crowning glory of man.

The widely-varying powers of resistance to toxic agents of the central nerve cells of different individuals is an important part of the difference in constitutions and temperaments, and has given rise to extremes of opinion. The neurotic fall an easy victim to the direct action of alcohol, while to the more stable, Crime is apt to stand as the child and Insanity as the grandchild of Intemperance.

Concerning the relation of alcohol to insanity among the non-criminal insane in Massachusetts, the State Board of Insanity has embodied on page 81 of their report for 1901 the aggregate statistics from five State hospitals, and the Boston Insane Hospital for the two preceding years. These statistics embrace 4,437 admissions, and the cause of insanity in 14.88 per cent. of these cases is given as intemperance. This may be taken as the most reliable information we have on the subject, but it must be remembered that statistics concerning the causation of insanity are confessedly unreliable for many and manifest reasons. On the one hand, members of the family refuse to acknowledge a bad heredity, and the patient is inclined to conceal bad habits. On the other hand, a single factor is commonly recorded as the cause of insanity when many factors have been potent influences. A neurotic organization—degenerating nerve cells—may cry for the anæsthetic effects of alcoholics, even as alcohol may cause this same degeneration.

The statistics referred to include both men and women, while alcoholism, as a direct cause of insanity, is about three times more common among men than women. A study of the statistics of the Worcester Hospital for Insane, the reports of which

†*Alienist and Neurologist*, January, 1901, page 197.

‡Clinical Psychiatry, translated by Deffendorf, pages 107-132.

§Mental Diseases, page 247-266.

evidence much pains in investigating causation, seem to show that alcoholism has been a sufficient cause of insanity in about 7 per cent. of the women and 21 per cent. of the men and a causal factor in about 10 per cent. of the women and 32 per cent. of the men admitted to that hospital. The poverty, overwork, stress, and worry, blighted hopes and consequent ill health, which follow in the wake of inebriety, are not debited to alcohol in these statistics. If these so-called "moral and mental" causes were traced back, the proportion of insanity charged to alcoholism might be much more equal between men and women.

THE MEDICAL OFFICER OF THE UNITED STATES NAVY.

By GILBERT TOTTEN McMASTER, M.D.,
NEW HAVEN, CONN.

THE navy is the nation's sea army. Officers and men lead a military life in their mobile castle of steel surrounded by the ocean. They are subject to the same military laws (with changes incident to the variety of service) that the army obeys. But the least understood of all officers of a battleship is the surgeon.

The United States Navy Medical Officer must be a "many-sided man." His literary and professional requirements are exceptionally severe. Uncle Sam demands men physically perfect and free from inherited taint. The young surgeon will ascertain that foreign languages, diplomacy, and elegance of manner are essential if he wishes to be an officer, gentleman, and a regular. The ships of the navy visit every quarter of our little globe. Diseases peculiar to climatic conditions will be encountered, and the surgeon must be master of the situation. All varieties of classified and non-classified conditions fall to his lot. As a broadening process, he has the advantage over his brother ashore to a certain extent.

Duties.—The duty of paramount importance is the health of the ship's company or station. On shipboard the surgeon must examine the sick bay dispensary, medical store rooms, holds, sleeping quarters, and water-tight compartments. His shore duty implies strict sanitary inspection of the Naval Hospital, its grounds and appurtenances thereof, together with the healthful arrangement of officers' quarters, marine barracks, and the naval prison, if the yard contains one. All boys, men and cadets, he must examine as to the physical qualifications for the service. He must ascertain if vaccination is required and perform the same. Food and water brought aboard in a foreign port, he must analyze as to its fitness for consumption by the ship's company. He must keep a medical journal of the entire cruise—subject any time to inspection by his captain or the ranking surgeon—and send it in quarterly with his report to the Bureau of Medicine and Surgery at Washington, no matter where his ship may be.

The captain shall be informed by him daily at 10 A.M., in writing, of the names and conditions of the sick.

The surgeon must, at all times, hold himself in readiness to attend the sick and wounded. He shall, when ordered, distribute tourniquets, and instruct both officers and men in their use. If an American merchantman applies for help in a foreign or home port, the surgeon must answer the summons, provided it does not endanger the health of his ship's company. Once every week the medical officer, in company with the executive, must personally inspect the holds, living spaces, and staterooms and report the same to his captain. The health of the crew he must always have in mind. Spirits and liquors, the property of the government, shall never been trusted to the care of enlisted men, except when needed for the sick, and then to be immediately consumed.

His surgical instruments, he cannot dispose of at his pleasure, but must institute a board of survey, who, if they see fit, will condemn and recommend later designs. When his ship goes out of commission after a long cruise, he must execute an inventory of all medical stores incident to a vessel of war and a medical officer, and transfer the same to the senior medical officer of the station.

[1]On entering a foreign port, the surgeon shall exhibit his bill of health of his ship's company to the medical officer of the port, and must make, in writing, a report of all diseases, epidemics, and other conditions peculiar to the place for transmission to the Surgeon-General of the Navy.

At summary court-martials where confinement is necessary, he must advise if the wayward Jackies' health will be impaired by restriction in diet.

Landing parties on foreign and savage shores are frequent. The surgeon's resources, packed in a small box, are all that is essential for emergency. Such are a few of the multifarious duties of a doctor in the navy.

The smallest cork, bottle, and piece of gauze being the property of his government, he is responsible for and must account for the same or stand the consequences.

When the order "clear ship for action" is trumpet-brayed and drum-vibrated through the ship, and the steam syren screams in weird vehemence "close water-tight compartments," and the rush of 500 to 600 men—the roar of the engines and of a sudden silence pervades all parts of the great ship, whose funnels are vomiting clouds of black smoke as she cleaves old ocean ready to fight—we find the surgeon calmly awaiting the gallant fellows from the decks above, that will be brought to him, screaming, mangled, and spattering blood as they come. While combating hemorrhages and binding up his patient, a shell may rip through the bulkhead carrying him and his man into eternity.

[2]Surgeon-General Rixey, U. S. Navy, observes "the first aid will have to be given on the battleships by medical officers in different portions of the ship. Most of the operative work will have to be done after the battle is over, which, in most cases between large ships, would be of short duration." The naval surgeon in a sea battle operates on a constantly heaving table. His decks, platform, or floor, whatever name it may be called, is not still a minute.

The recoil of the great guns is transmitted to all parts of the ship, severe trembling ensues, hence a steady hand, quick ratiocination, perfect instrumentality, commensurate to the incessant heaving and throbbing, are essential.

[3]Mr. Richard Harding Davis, in his excellent little work, mentions the surgeons so handsomely in his inimitable style that the profession owes him a debt of gratitude. He says: "Taylor, a young gunner's mate, was shot on April 26 (1898) by a revolver. It was an accident, but it is possible he was more seriously hurt than was any of the six wounded men who went through the seven hours' battle at Manila. Junior-Surgeon Spear said that if he had tried to dodge the vital parts in Taylor's body with a surgical instrument, he could not have done it as skilfully as did the bullet, which was neither aimed nor guided by human hand. It was Junior-Surgeon Spear who performed the operation, while the fleet surgeon, Dr. Gravatt, watched him and

advised. It was a wonderful operation. It lasted nearly two hours, and it left the layman uncertain as to whether he should the more admire the human body or the way a surgeon masters it. What they did to Taylor I cannot tell in technical language, but I know they cut him open and lifted out his stomach and put it back again, and sewed him up twice . . . that these parts of himself had been picked over and handled as a man runs his fingers over the keys of a piano and had then been pushed and wedged back into place and covered over as one would sew a patch on an old sail, to lie hidden away again for many, many years more."

The operation herein described was a success. The boy recovered.

Abdominal surgery under the most favorable conditions is delicate work.

[4]"The slightest deviation means unnecessary damage, perhaps death to your patient."

[5]Rear Admiral R. D. Evans, U. S. N., gives unstinted praise to the surgeon who attended him. He observes: "My shoulder was badly smashed and dislocated, but the excellent medical men soon wiped the blood off and reduced the dislocation."

[6]During the chase of the *Colon* by the *Brooklyn* on July 3, 1898, we find Dr. DeValin, U. S. N., was so near Yoeman Ellis that when the latter was killed he was spattered with his blood. The medical officer is not always out of harm's way as some have asserted.

The surgeon in our large cities does his work on a steady foundation. No extraneous uproar will blight the fair prospect of his success.

Nurses, assistants, good lights, and solutions abound—in fact, every appliance known to the curative art are at his command, and when his work is done he is aware that perfect rest will be obtained for his patient.

If one imagines when observing the great white ships of our navy gliding majestically through the ocean, that all is quiet aboard, let him change his mind. A warship of to-day seems almost a sentient being, mechanical devices are its nerves and arteries, its mentality, electric forces. Here, surrounded by dangers that a reckless "laying on of hands" may start into activity, dwell our officers and men. The surgeon, a silent, thoughtful entity, is quietly watching his portion of this little world, the living part of the machine.

On shore stations, navy yards, there may be found extensive machine shops and a well-equipped naval hospital. Injuries incident to machinery abound. The families of the officers give ample variety for medical work—particularly the women and children. So, ashore, his duties are not lightened but multiplied. In Washington a naval medical officer is always stationed to attend to the families of the officers. The present incumbent, being one of the most distinguished in the corps, Medical Inspector William S. Dixon, U. S. N. At all official receptions, whether ashore, shipboard, foreign service or at Washington, the medical officer must carry out his part of the program with his brother officers, the gentlemen of the line.

As he "ships" with line officers, he makes many friends that are life-long.

If he is taken away, the brothers of his corps and these same line officers, stand by his widow and children—an impenetrable, honorable, and sturdy wall of loyal friendship that is never tarnished by the ravages of time.

If he gains the age limit, his rank is commensurate, and when Uncle Sam politely, gently, and gratefully tells him he is sixty-two years old, he finds himself honored and respected, a retired officer and a gentleman of the navy of the United States.

Deaths from Typhoid Fever in Cleveland.—A study of this subject made by Geo. W. Moore reveals the following statistics: (1) Typhoid fever in Cleveland furnished during the thirteen years under consideration, three per cent. of the total deaths (excluding deaths of non-residents and still-births). The number of deaths reported by the Health Department in the same period was 2.5 per cent. of the same total. The mortality was 56 to each 100,000 of the average estimated population. (2) Nineteen per cent. of all tuberculous deaths occur between the years twenty and twenty-five, 36 per cent. between twenty and thirty, and 50 per cent. between 18.5 and 35.4 years. (3) One and eight-tenths per cent. of all deaths were male deaths from typhoid fever. Fifty-eight and one-tenth per cent. of all deaths from typhoid fever were male deaths. (4) One and two-tenths per cent. of all deaths were female deaths from typhoid fever. Forty-one and nine-tenths of all deaths from typhoid fever were female deaths. (5) In proportion to the total, the greatest number of deaths, both for males and females, is found in the five-year period between the ages of twenty and twenty-five years. (6) In proportion to the living population by age the greatest number of deaths occur between twenty and twenty-five years. In this respect the mortality of typhoid fever differs essentially from that of tuberculosis, in which the highest mortality is found well past middle life. (7) On the basis of this study, there is, presumably, no relation between the conjugal condition and death from typhoid fever, unless it be in a moderate increase in liability to infection on the part of the unmarried, and this, if it exists, is thought to bear equally on the two sexes.—*Cleveland Medical Journal*, May, 1903.

Ruptured Traumatic Aneurysm of the Subclavian Artery.—H. C. Hinder relates the history of the case, the patient being a man, aged twenty-two years, who had been stabbed with a knife just above the outer end of the left clavicle. He was intoxicated at the time and did not know what had been done, but was told that a handkerchief had been stuffed into the wound. The cut healed and he returned to work, but a lump soon formed about the site of the wound and rapidly increased in size, causing extreme pain and giving evidences of pressure and circulatory impairment in various directions. A harsh bruit could be heard over the swelling, but there was no pulsation therein. Under incision no distinct vessel could be isolated, so the operator decided to open directly into the sac. This was broken through with the finger, the blood-clot scooped out, and then the fingers thrust down on the site of the hemorrhage. All this occupied but three or four seconds but the patient became blanched through loss of blood. Forceps, and, later, ligatures were applied on each side over what proved to be a slit two-thirds of an inch long in the third part of the subclavian artery. The wound was kept as clean as possible. Secondary bleeding occurred one month later but was stopped by plugging. Six months after the operation the patient was doing very well, though there was a complete loss of motion and sensation in the whole of the hand, sensation ceasing just above the wrist. The operator believes that either the forceps or the subsequent ligatures included some branches of the brachial plexus.—*Indian Medical Record.*

THE ETIOLOGY OF VARIOLA.

THE latest issue of the *Journal of Medical Research* gives an account of the recent studies of Councilman and his assistants upon this topic. Reference is made to the work of Guarnieri in 1892 who described in the lesions of both vaccinia and variola, certain peculiar inclusions in the epithelial cells. These have been variously regarded as organisms, leucocytes, or fragments thereof, and as degenerative products peculiar to the disease. Wasielewski, whose work is of primary importance, considered them to be organisms.

The views of Councilman are embodied in the following statements: "In the lower layers of skin epithelia, before there is present any anatomical evidence of vesicle formation there are found small, structureless bodies from one to four microns in diameter. The cells present, at this time, little or no evidence of degeneration. The bodies, one or more in number, lie in vacuoles in the cells. The vacuoles are, at first, but little larger than the inclosed bodies. The bodies increase in size and evidence of structure, consisting of granules more distinctly stained, and lying in definite spaces, begin to appear. With the increase in size of the body, the vacuole of the cell enlarges until a large central space around the nucleus is formed. At this time there is but little evidence of degeneration of the nucleus. The body continues to increase and becomes granular, the granules lying in a reticular structure. The form of the larger bodies is irregular and suggest an amœboid character. They may become as large as or larger than the nucleus of an epithelial cell. A definite nucleus has not been made out in them, unless the reticular structure which stains more intensely than the rest of the body be so considered. At this time segmentation takes place, leading to the formation of small, round bodies about one micron in diameter. All this is best seen in the acute hemorrhagic cases. It may also be seen in the advancing edge of a young vesicle, the bodies becoming larger and more definite in structure as the formation of the vesicle advances. The bodies in the cells we regard as living organisms, and the gradual growth and final segmentation as a cycle in its life history. Up to this time the nuclei, although showing such evidences of degeneration as the massing of chromatin in the periphery, are not greatly altered."

"At the period of segmentation, and when most of the intracellular bodies have disappeared, small round or oval ring-like bodies appear in the nucleus. These increase in size and acquire a definite structure, consisting of a series of vacuoles around a large central vacuole. The rim of the central vacuole stains more distinctly than do other parts of the body. One or more of these bodies may appear in a single nucleus. When several are present they are smaller, but have the same structure. The bodies become larger, the nuclear rim grows less distinct, and finally disappears,and the body lies in a completely degenerated cell, or this breaks down, setting free the body. With the growth and development of the intranuclear body, the vacuolar structure becomes less evident, and finally a structure is formed which contains numerous fine vacuoles. At this time small circular bodies begin to appear in it, and groups of these are surrounded by a faint ring, which probably represents the remains of the body in which they were formed."

Councilman regards this intranuclear body as a further stage of development of the intracellular body, and as representing a second complete cycle of development. It develops from the spore-like bodies produced by the segmentation of the intracellular body which pass into the nucleus. In a case of hemorrhagic smallpox, he has found bodies similar to these spores in a blood vessel of the skin. He also regards it as extremely probable that in smallpox the complete development of the parasite through two cycles occurs, and that in vaccinia only the primary cycle. Certain forms of the intranuclear bodies would seem to show that the intranuclear cycle is sexual in character.

While all these statements are made with the caution of the careful observer, they mark a distinct advance in our knowledge of the etiology of a disease which has always been a source of dread to the laity, and which has always presented to the profession many baffling problems. If the modest prophesies of the Boston investigators shall prove true, they will have conferred upon themselves a well-earned renown and shed lasting glory on American medicine.

IS GENERAL PARALYSIS OF BACTERIAL ORIGIN?

GENERAL paralysis is probably better known to the non-alienist than any other form of insanity. This fact, together with its great frequency in the community, and the hopeless prognosis which attaches to a correct diagnosis, renders the subject one of general interest. Its causation is by no means settled, though the theory that it is a post-syphilitic affection, has many advocates. The line of evidence generally relied upon is the greater frequency of the disease in communities, and among classes in which syphilis is common, and *vice versa*, the occurrence of the disease in both husband and wife, etc. And certainly the evidence thus afforded is sufficient to make out a plausible case. On the other hand, there are alienists who believe that syphilis has nothing to do with general paralysis. The paper of Drs. W. Ford Robertson, McRae, and Jeffrey, in the *Review of Neurology and Psychiatry* for April, 1903, therefore has considerable importance, as the authors believe that they have found a bacillus which may well stand in causal relation to the disease. Their former investigations seemed to show that the toxæmia of general paraly-

sis is of gastrointestinal and bacterial origin, and that the rôle played by syphilis, alcohol, lead, etc., in the pathogenesis of the disease, is an indirect one, those agents operating in the direction of an alteration of the natural immunity. In the present series of experiments they sought to determine whether the bacterial flora of the intestinal tract possessed any distinctive features, and whether microorganisms were present in the blood and internal organs. A number of cultures from the blood were uniformly sterile, and this line of work was abandoned. Preliminarily, and pending fuller publication, they are, however, able to record two outstanding facts: First, there is evidence that not only the alimentary canal, but also the respiratory tract, is the seat of origin of a severe toxic infection. Secondly, there is one microorganism which appears to have a special significance by reason of the constancy of its presence, its enormous numbers, the frequency with which it takes part in a terminal general invasion, the known pathogenic character of the group to which it belongs, and the comparative rarity with which, with the same technique, a similar organism can be isolated from other cases. The organism in question resembles the Klebs-Loeffler bacillus, but is not Hoffman's bacillus. It is most readily obtained from the mucous surfaces of the stomach, tonsils, and bronchi. Rats fed for several weeks upon pure cultures, showed no symptoms during the first three or four weeks, but after this they exhibit especially slowness and uncertainty of gait, and drowsiness after feeding. Later they show distinct motor weakness, marked incoördination of movement, dyspnœa, great drowsiness, looseness of the stools, and death. The pathological changes observed are gastrointestinal catarrh (especiallymarked in the upper portion of the small intestine), proliferative and degenerative changes in the liver, and evidence of inflammatory changes in the lung. In the nervous system, severe degeneration of a large proportion of the cells of the cortex, early acute periarteritis, proliferation of the neuroglia and mesoglia, and infiltration of the pia-arachnoid are found. The cord shows similar changes, the degeneration of the cells being more pronounced. Many nerve fibers show distinct alterations by both the Marchi and Weigert-Pal methods. Thus when introduced by the alimentary canal, the bacillus in question is capable of producing changes especially affecting the nervous system, and changes which, once set up, can go on to death, even though the feeding be stopped. The changes in the nervous system have a distinct resemblance to those seen in general paralysis. The authors themselves say that their work in its present phase does not amount to demonstration, but their results are, nevertheless, interesting as a first approximation to the solution of a much-vexed question.

CHLOROFORM VERSUS ETHER.

Of all the international medical questions of the nineteenth century, none was waged with more pertinacity, not to say acrimony, than that over the respective merits of the two principal anæsthetics. It is, therefore, somewhat interesting to read the results of the observations of four of our English confrères in the *Journal of Physiology* for March 21, 1903. Tunnicliffe and Rosenheim operated by the method of perfusion—that is, by passing through the excised heart a suitable nutrient fluid which was oxygenated in bulk before the beginning of each experiment. The anæsthetic was accurately weighed and dissolved in the nutrient fluid. The latter was freshly made up before each experiment, and all necessary precautions were taken to prevent evaporation. Under these conditions, perfused through the heart in very small quantities, pure chloroform in the proportion of from 1:100,000 to 1:25,000, caused slowing, and slight increase in the amplitude of the pulsations. The heart so affected could always be brought back to the normal by re-perfusion with nutrient fluid to which no chloroform had been added. Stronger solutions (1:10,000) caused slowing, sometimes irregularity, and always marked diminution in the amplitude of the pulsation. Solutions of from 1:5,000 to 1:2,500 affected the heart seriously. Pohl determined the amount of chloroform in the blood of narcotized animals as from 0.018 to 0.040 per cent. If this limit be exceeded cardiac arrest quickly results. Pohl further showed that in cases of cardiac arrest by chloroform, the latter is present in the proportion of 0.06 per cent., which leads Tunnicliffe and Rosenheim to point out the very close agreements of their results with his (the proportion of 1:5,000 to 1:2,500, corresponding to 0.02 to 0.04 per cent.), and further how small is the difference in the amount of chloroform required for the production of narcosis, and that which will involve cardiac arrest, that is how small is the margin of safety. On the other hand, both Franz's experiments and their own, showed that the amount of ether present in the blood during narcosis is not sufficient to affect the heart. Franz found the amount to be 0.5 per cent., and the authors found that ether in the proportion of 1:500 did not produce any serious effect. The effect of strong and weak solutions alike was to produce at first irregularity and slowing, but the effect was quite transient. Parenthetically, solutions of alcohol produced similar results; transient slowing and very slight irregularity, much less marked than with ether, and the heart could be perfused a relatively long time without further alteration in its action.

Schafer and Scharlier investigated the action of chloroform, inhaled and injected into the blood vessels in normal salt-solution, upon the heart of dogs. They insist upon the specific nature of the action of the drug upon the mammalian cardiac muscle, pointing out that after the heart has been brought to a standstill (and this condition may occur almost instantly, but is more common after the lapse of a minute or two) the condition of the muscle is such that no kind of stimulant action, direct or indirect, will elicit any response. The heart is in diastole, with the cavities more or less full ("paralytic dilatation"). The authors think, however, that it is more than a condition of mere paralysis, for a paralyzed muscle will still respond to direct stimulation. But here the irritability of the muscle itself has disappeared, and the muscle is in a permanently refractory state, associated not with systole, as in the ordinary refractory phase, but with diastole. This condition, which renders the drug especially dangerous in inexperienced hands, is, in their opinion, one of ex-

citatory inhibition. It is, however, not of vagal origin (either central or peripheral), as it persists after section of the vagi, and after the administration of atropine. That the action of the drug is specific on the heart is shown by the persistence of excitability in the other muscles of the body.

Medical Representation in Hospital Management.

The question as to whether medical men should be represented on the board in hospital management, has been for long a much disputed point, a point concerning which, members of the medical profession are not agreed. For so many years doctors have been persistently told they are not business men, that a large number of them now regard the statement as true, and for this reason do not, as a rule, proffer their services to aid in the management of hospitals. Whatever may be, however, the medical man's ability in the transaction of the ordinary affairs of this world, and even granting that he is not generally a shining example as an exponent of modern materialism, yet one would be led to think that he should at least be a success in the management of a hospital. This matter was referred to in the Medical Record of June 6, in commenting on the eloquent address delivered at Washington on May 12, by Dr. Keen as President of the Sixth Congress of American Physicians and Surgeons.

Dr. Augustus A. Eshner of Philadelphia read before the American Academy of Medicine, on June 9, 1902, a paper treating of the same subject. Dr. Eshner says "to such proportions has the fallacy with regard to the inability of medical men to participate successfully in business affairs grown, that certain lay boards of hospital management have permitted the opinion to go forth that hospital management is a matter of pure business, and that the medical officers are to be looked upon as mere subordinates, to receive and to carry out the directions of their superiors, the lay managers. "There has, it seems to me," the writer goes on to say, "occasionally been too ready assent to this proposition on the part of medical men and others, to the detriment, I am sure, of the institutions in which the ideas under consideration have prevailed."

Coöperation between the hospital managers and the medical staff is absolutely essential to the usefulness and prosperity of the institution. Business matters, generally, may be left in the hands of the lay managers, while professional matters may surely be left with confidence to the discretion of the medical staff. According to Dr. Eshner, there are several ways in which satisfactory representation can be given the medical staff on the board of management of a hospital: (1) By electing one or more members of the staff to membership in the board; (2) by periodic conferences between the staff and the board; (3) by conferences between a committee of the staff and the board or a committee of the board. It seems absurd that medical men should have no voice in the management of the institutions to which they are attached. This view is based quite as much on the interests of patients as on those of doctors.

Alien Immigration.

This is not the only country in which the problem of immigration presents itself in perplexing forms. Of course, more persons emigrate to the United States than to any other land, and the class of those who come now is not nearly so desirable as was once the case, but at the same time a certain amount of restriction is placed upon the entrance of these would-be American citizens, and regulations are enforced which keep out the diseased and absolutely worthless. In Great Britain, on the contrary, the time-honored policy is still carried out of allowing immigrants from other nations, of every class and condition, to settle without let or hindrance upon her hospitable shores. This policy is now beginning to give rise to a good deal of grave doubt and misgiving, and the authorities are asking themselves if it really be the wisest course, to allow the scum of Europe to make their home in England, and eventually probably to become a burden to the rate-payers. The *Sanitary Record*, writing on the subject, and with special reference to a report recently issued by the Alien Immigration Committee, on the condition of foreigners in the East-end of London, says: "There is no doubt that these immigrants who are largely Russian and Polish Jews, come to this country not only destitute of sanitary notions, according to our English standard, but in a condition that is a serious menace to our countrymen." Here is a description of them by a writer who has been making a special study of the matter: "They may be decrepit wastrels; they may have infectious disorders; their frames may be rotten with horrible diseases; but so long as they have not yellow fever, the plague or cholera. they are allowed to land and to go whither they will, . . . These incomers to England probably never had a bath in their lives. They leave Russia dirty, with no disinfection of their clothing, and no inspection as to their physical condition. When the vessel arrives in the Thames, the Health Officer goes out in a launch to meet it. but if there has been no epidemic, he may accept the report without going aboard, so that immigrants suffering from many disorders come to England without hindrance. There is no law to turn back cases of smallpox, scarlet fever, measles, diphtheria, or indeed, anything but plague, yellow fever, and cholera. The outbreak of smallpox a year ago originated abroad. When the unwashed, verminous alien lands, he goes off to his friends in the over-crowded East-end. Even when en route to America, he is without inspection as to physical condition; allowed to travel from Hull, Grimsby, and London in English railway carriages, which are afterward subjected to nothing but the ordinary sweeping out."

This is a severe arraignment of the methods of the British health authorities, and, if literally true, would seem to bear evidence of a carelessness regarding the public health inconsistent with national reputation in such matters. It may be, however, that England will find it to her advantage to take a leaf from America's book, and to frame more stringent laws with regard to alien immigration.

Smallpox in England.

The recrudescence of smallpox in England, and especially in London, on a somewhat large scale, has naturally given rise to a considerable amount of literature on the subject in that country. As smallpox has been now for some time present in the United States to a greater or lesser degree, any information treating of the matter cannot fail to be of interest. The report of the Metropolitan Asylums Board for 1901, on the London smallpox epidemic, given in the *British Medical Journal*, December 6, 1902, is a document of some import. It states that errors in diagnosis were remarkably frequent. These are due, it is said, to the fact that medical men now certify cases which are only suspected, such as contacts, who show some febrile disturbance, and who are notified before the eruption appears. Out of

1,845 cases certified by London medical men as smallpox, no fewer than 237, or 12.7 per cent., were found by the experts to have some other complaint. Chickenpox is, of course, the affection most often mistaken for the graver disease. Of the 237 cases of mistaken diagnosis mentioned above, 77 were chickenpox; acne numbered 25 cases; dermatitis, 18; syphilis, 17; urticaria, 14; eczema, 11; furunculus, 10; 9 each of vaccinia, and acute non-eruptive infectious diseases; 6 each of drug rashes and febricula; 5 each of impetigo and lichen; 4 each of scabies, scarlet fever, and measles; herpes, 3, and pemphigus, 2. The statistical tables show that of 1,282 vaccinated cases of all ages and degrees of vaccination, 127 died, or barely 10 per cent. Of 307 unvaccinated cases, 119 died, or over 38 per cent. The earliest age at which an unvaccinated child was attacked was between 3 and 4 years. It had unfoveated scars, less than one-third of a square inch in total area. The total number of vaccinated cases under 10 years of age was 20, and all recovered. The earliest age at which a death of a vaccinated patient occurred was between 10 and 11 years. The next most fatal cases among the vaccinated were between 15 and 20 years of age. The fatality rate of the vaccinated advances at later age-periods. Of 225 cases between 20 and 45 years, there were 15 deaths, or 6.6 per cent.; 226 cases between 25 and 30 years, 17 deaths, or 7.5 per cent.; 170 cases between 30 and 35 years, 20 deaths, or 11.8 per cent.; 142 cases between 35 and 40 years, 26 deaths, or 18.3 per cent.; 147 cases between 40 and 50 years, 34 deaths, or 20.3 per cent. After the age of 50 the death rate decreases. Among the unvaccinated, however, the earlier years of life had many cases and many deaths. Under 1 year, 24 cases and 17 deaths; in the second year of life, 31 cases and 10 deaths; in the fifth year, 20 cases and 6 deaths. Out of a total of 372 unvaccinated cases no less than 192, or over 51 per cent., were under 10 years of age, while in a total of 1,282 vaccinated cases only 20, or less than 2 per cent., were under 10 years of age. Among the unvaccinated in a total of 119 deaths, 65, or over 54 per cent., were in patients under 10 years of age; whilst of the 127 deaths at all ages among vaccinated, not a single death occurred in children under 10 years of age. The statistics here quoted afford yet further proofs—if proofs were needed—of the efficacy of vaccination. They also emphasize a fact to which attention has often been called in the MEDICAL RECORD, that the ordinary medical practitioner is extremely apt to make errors in diagnosing smallpox.

ÆLUROPHOBIA.

The announcement made recently by Dr. Weir Mitchell that he is studying what is known as "cat fear" has impelled a writer in the *Bookman*—probably the editor, Prof. Thurston Peck, himself—to make some very apposite remarks on the subject, as well as to suggest a name, strictly technical, for this peculiar idiosyncracy. The name proposed, ælurophobia, is declared to be a good Greek compound, and one over whose construction those responsible are modestly complacent. "Cat fear" is a curious nervous state into which some persons are thrown at the sight or even unseen presence of a cat. This sensation has no connection with physical fear, for some of the bravest of men are subject to it—witness Lord Roberts. The feeling is one of repulsion or loathing. The theory held by the writer in the *Bookman* is that "cat fear" is only a secondary manifestation of serpent fear, and he writes on the matter thus: "The peculiar loathing which the white man feels for the snake extends, in highly sensitive natures, to creatures or even inanimate objects which resemble or suggest the snake. Thus most persons shudder and shrink back when a large eel is thrown writhing at their feet. They know perfectly well that it is not only a harmless creature, but that it is not a snake at all; yet they would not touch it and few care to eat it. As to inanimate objects there are many which are sufficiently condemned when they have the adjective snaky applied to them. Snaky locks, snaky ringlets, snaky movements—all these, and a score of other expressions, connote something repulsive. Now the cat is essentially a snaky creature. Most of us do not realize this because we lack the observing eye and the instinct of comparison, and, moreover, we are not troubled with hyperæsthesia. But to watch a cat as it moves about at ease, as it lies in the sun, or as it curves itself into its usual position when about to sleep; its stealthiness, its sinuous movements, the undulations of its lithe body—these are closely comparable with what we notice in the serpent, and if the cat have glossy fur, and if it be barred with stripes, there are moments when the resemblance is so striking as almost to make us shiver. Many persons feel this at times, but only in a momentary way. Other persons, however, are conscious of it all the while, or at least are conscious of a feeling of repulsion which they cannot explain, but which, in reality, represents the serpent dread. the loathing of the snake and all that suggests the snake, even when the mind is not aware of the underlying reason. This dread is, we believe, the dread to which Dr. Mitchell has given the name "cat fear." It may be called "cat fear, but in the last analysis it is a secondary manifestation of snake fear." This theory is at any rate plausible, but whether it will commend itself to Dr. Mitchell as a satisfactory explanation of that nervous condition which renders certain persons peculiarly susceptible to "cat fear" is another matter. There can, however, be no objection to the name ælurophobia; it is no doubt much more fitting than are most of the hybrid terms given to diseases. Professor Peck is a distinguished classical scholar, and vouches for the fact that the word is a good Greek compound.

THE METHODS OF QUACKS.

The manner in which quacks attempt to throw dust in the eyes of the public would be amusing, were it not so often attended by painful results. There is no deception that an unscrupulous member of this fraternity will not undertake in order to make money. No trick is too heartless for an individual of this character to put into effect so as to gain his object.

Dr. Knopf, speaking of the methods of such charlatans, a short time ago, mentioned a glaring instance which came under his immediate notice. A poor woman in the last stages of consumption came to him seeking advice. When asked for the name of her former medical attendant, she confessed that she had been treated for a number of weeks by a quack concern, and now that her means were exhausted, she was given to understand that they would not continue to treat her unless she would give them a certified testimonial that she had been thoroughly cured of her disease. Some of these men will resort to fraudulent measures to enable them to gull the public. A notorious example of this barefaced practice has been carried on in New York City for a considerable time. A firm of quacks advertise Dr. Robert Koch as if he were associated with them in business, and were exploiting his treatment. The Committee on the Prevention of Tuberculosis of the

Charity Organization Society, in order to be able to give an official denial to these statements, wrote to Dr. Robert Koch on the matter and, of course, received from him a most emphatic and indignant repudiation of having any dealing with the concern. The Committee on Tuberculosis of the New York Charity Organization Society has been used by some of these firms as a stalking-horse to delude the public with, and the misuse of the committee's name and of some of its members became so intolerable that, a short time ago, resolutions were adopted by the committee, couched in vigorous terms, in which the fact was pointed out that there is no specific remedy for consumption, and that such statements are made merely with the view of deceiving poor and frequently ignorant consumptives. It is to be hoped that the outspoken declarations of the committee may have the effect of at least deterring some from wasting time and money in the vain hope of receiving benefit from quack medicines.

The Use of Acid Phosphate of Sodium in Alkalinity of the Urine.

Dr. Robert Hutchison, assistant physician to the London Hospital, writes on this subject in the *British Medical Journal* of June 6. For some years he has been making investigations on the behavior of acids and alkalies in the body, and has also made experiments on the influence of different drugs on the reaction of the urine. He tried in particular to determine what agents are best adapted to increase the acidity of the renal secretion. The method adopted was to estimate the acidity of the urine secreted during the night by an individual on a fairly fixed diet, on several successive occasions, so as to obtain a standard of normal acidity. The substance, the effect of which was to be tested, was then administered at bedtime, again on several successive occasions, and the average urinary acidity obtained compared with the standard already observed under normal conditions. The acidity of the urine in these experiments was estimated in two ways: (1) By the method of Freund, which consists in throwing down the alkaline phosphates by barium chloride and subsequently estimating the acid phosphates by titration with uranium nitrate solution. (2) By direct titration with standard alkali solution; phenolphthalein being taken as the indicator. Observations were then made with mineral acids—hydrochloric, sulphuric, and phosphoric—and it was found that the influence of these, even in the largest doses that could be conveniently administered, was extremely slight. Next, organic acids were used, of which were tested, tartaric, acetic, citric, and lactic, these had a slight but distinct tendency to increase the acidity of the urine. Thirdly, benzoic and boric acids were found to exert no influence on the reaction of the urine, and, lastly, acid salts were tried, especially phosphate of sodium. This salt had a more direct and marked influence on the reaction of the urine than any other substance tested. The result compiled from the averages of many observations, showed that by no means all the acid phosphate is excreted in that form, but that a considerable portion is neutralized in the body, while the ammonia output is decidedly raised after the administration of the acid phosphate. Dr. Hutchison then tried the effect of acid sodium phosphate in alkaline urine, with the result that the power of the drug to increase the acidity of the urine was made quite manifest. The writer says that the drug has been used during the past two years in cases of alkalinity of the urine, from cystitis and other causes, with satisfactory results. The acid has the advantage of being very soluble in water and easily administered, and may be given in doses of from 30 to 60 gr., every 3 hours, although smaller doses administered more frequently have a better effect in securing continuous elimination.

Malignant Endocarditis Giving Widal's Reaction.

Dr. W. Hale White records a case of this nature, which was under his care in Guy's Hospital, London. The patient was a girl of seventeen years, who was in the hospital for three months suffering from malignant endocarditis, at the end of which time she died. Dr. White gives a brief history of the case on account of the unusual bacteriological findings, and because of their clinical interest. Streptococci were easily found in the blood, and about a month before death the agglutination test was tried with five strains of the B. typhi abdominalis, and in a strength of 1 in 20 four out of these strains were agglutinated by the serum of the patient.

At the necropsy which followed the death of the girl, examinations were made of the blood from the right and left ventricles and of the spleen. From the blood collected from the ventricles the streptococcus longus was obtained in pure culture. From the spleen the same streptococcus was isolated, and the B. coli communis. All attempts to isolate the B. typhi abdominalis, however, failed. Thus the only evidence that the case was one of enteric fever was that the patient's serum reacted with four different strains of B. typhi abdominalis during one period of the disease. There were never at any time intestinal ulceration nor spots, and the negative examination of both blood from the spleen and urine gives, thinks Dr. White, conclusive proof that this patient had not had typhoid fever. She likewise had not suffered from typhoid fever previous to her coming to Guy's Hospital, for she did not give the reaction when first admitted.

"Thus," sums up Dr. White, "we have an undoubted case of a patient suffering solely from malignant endocarditis of streptococcal origin, and yet during the progress of the disease, she developed in her blood-serum certain substances which had the power of—in a strength of 1 in 20—agglutinating the B. typhi abdominalis." "This," says Dr. White, "is of considerable importance, not only in considering in any case the diagnosis between malignant endocarditis and typhoid fever, but also because one of us has examined many cases of ulcerative endocarditis, and, like many authors who have published their results, has hitherto failed to obtain a Widal reaction in this disease."

The Use of Phosphorus in Matches Condemned.—The International Chemical Congress, in session last week in Berlin, adopted a resolution favoring an international agreement prohibiting the use of phosphorus in making matches, and requesting the international committee appointed at Paris in 1900 to communicate the resolution to the various governments

Another Consumption Cure.—At a recent meeting of the Berlin Medical Society, a paper was read on the treatment of pulmonary tuberculosis by the inhalation of the fumes of a mixture of eucalyptus leaves, sulphur, and charcoal. The mixture is made according to a special formula and bears a proprietary name. The usual report was made that the appetite improved, fever subsided, and bacilli disappeared from the sputum.

News of the Week.

Livingston County (N. Y.) Medical Society.—At the annual meeting of this society held at Geneseo June 9, the following officers for the coming year were elected: *President*, Dr. W. P. Spratling of Sonyea; *Vice-President*, Dr. J. H. Strassenberg of Avon; *Secretary*, Dr. H. G. Squires of Avon; *Treasurer*, Dr. G. C. Jones of Geneseo.

Inspection of Milk and Meat in Philadelphia.—Rules adopted by the Philadelphia Department of Health have been approved by the Mayor after conference with Dr. Edward Martin, Director of the Department, Dr. A. C. Abbott, President of the Bureau of Health, and representatives of the Milk Commission of the Philadelphia Pediatric Society and of the Keystone Veterinary Medical Association. These rules require that all dealers in milk must be licensed, all dairies inspected monthly, all milk and cream tested chemically and bacteriologically, and that milk dealers should sterilize all bottles before these are used for the delivery of milk. All meat-producing animals must be inspected by a veterinarian of the Department of Health before being killed, and all meat exposed for sale must bear the stamp of the Department.

Philadelphia County Medical Society.—At a stated meeting, held June 10, Dr. Mordecai Price exhibited a specimen of carcinoma of the bowel removed by surgical operation. Dr. Augustus A. Eshner read a paper entitled "The Management of Fever in General." Dr. J. Madison Taylor presented a communication entitled "Some Remarks on the Treatment of Paralysis Agitans." Dr. Robert N. Willson read a paper on "The Significance of Urinalysis in Pregnancy, with Special Reference to Eclampsia."

The Philadelphia Medical Journal, one of the periodicals founded by Dr. G. M. Gould, has been sold to the publisher of the *New York Medical Journal* and will be consolidated with that paper. The publication office will be in this city, but it is stated that a business and editorial office will be maintained in Philadelphia. In his valedictory, appearing in the issue of June 13, the editor announces that with that issue the management of the paper passes out of the hands of the staff which has conducted it for two and a half years. During that time, he says, the editors have been actuated solely by the desire of conducting the journal entirely in the interests of the medical profession and for the advancement of scientific medicine. We had supposed such were the motives of all honorable medical editors, but possibly the writer had his eye turned toward a universal critic in his vicinity who has always claimed a monopoly of this guiding principle. "The members of the editorial staff," he continues, "in resigning their functions would simply call attention to the fact that they have been responsible for the editorial control alone of this journal, and they relinquish their trust with the consciousness that they have discharged their duty with every effort to meet their literary and professional obligations. We think it is not inappropriate or unconventional that we should make this statement as a brief valedictory announcement." The editorial staff was composed of Drs. James Hendrie Lloyd, editor in chief; Julius L. Salinger, associate editor; and Joseph Sailer, F. J. Kalteyer, D. L. Edsall, T. L. Coley, John M. Swan, W. A. N. Dorland, J. H. Gibbon, T. M. Tyson, M. Ostheimer, A. Robin, F. T. Stewart, P. B. Bland, and R. L. Fielding, assistant editors.

The Eye, Ear, and Throat Society of Washington.—At a meeting of this society, held May 22, the following officers were elected to serve during the coming year: *President*, Dr. Walter A. Wells; *Vice-President*, Dr. W. N. Suter; *Secretary* and *Treasurer*, Dr. H. O. Polkinhorn.

Dr. J. Elliott Colburn has been elected professor of ophthalmology in the Chicago Eye, Ear, Nose and Throat College.

A Report on Malaria.—A parliamentary paper issued in London last week, and summarized in a cable despatch to *The Sun*, reviews the progress of the investigation into malaria and other tropical diseases which has been carried on in connection with the School of Tropical Medicines, opened in 1899, largely on the initiative of Colonial Secretary Chamberlain. The several investigations were carried on by Dr. Daniels of British Guinea, Dr. Stephens of Cambridge, and Dr. Christopher of Liverpool. Dr. Daniels, who went to India in 1895, confirmed Ross's theory in every particular. Drs. Stephens and Christopher, in Central Africa and on the west coast made the important discovery that while a native adult in such regions was in a great measure immune from malaria, the disease was exceedingly prevalent among native children, and proved that in these regions the native is the prime agent in the infection of Europeans. The segregation of whites and natives and the avoidance of native huts are potent means of the prevention of the disease. In 1901 they went to India, and there they found, as in West Africa, that the native children have the parasites in their blood, and they must therefore be regarded as a source of infection. They maintain that in any district the percentage of native children infected with the parasite may be taken as an index of the prevalence of malaria, or of malarial endemicity.

Physicians Arrested.—A number of physicians in this city have been arrested on complaint of the Health Commissioner, charged with taking money from patients in pay for diphtheria antitoxin obtained free from the Board of Health. The technical charge was petit larceny. The accused doctors claim that they made no charge for the antitoxin used, but that the money received was the legitimate fee for the professional visit, and the operation of injecting the serum.

The National Bureau of Medicines and Foods.—The joint committee of the American Medical Association and the American Pharmaceutical Association, appointed to consider the desirability of establishing this bureau, has prepared a plan which is published in full in *The Druggists' Circular* for July. It is proposed to establish an incorporated society with control in a board of ten directors, five appointed by each of the associations above mentioned.

Any manufacturer desirous of having one or more of his products placed under the supervision of and certified by the bureau, must first apply to the secretary for associate membership, which application will carry with it a contract to abide by the rules of the bureau. The application will then be submitted to the board of directors, and on the written approval of a majority of them, such manufacturer will be accepted in associate membership. An associate member desiring to have a given product certified by the bureau, must transmit to the secretary a proper application for that purpose, together with two samples of the product in question. One of these samples will be sealed and deposited in the custody of the secretary; the other will be transmitted to the scientific department of the bureau, together with instructions to investigate fully the article, and to compare it with at least two samples bought in open market without the knowledge of the manufacturer. If found satisfactory, the board, in conjunction with

the manufacturer, will determine standard of identity, purity, quality, and strength, to which this product must thereafter comply, and will formulate rules acceptable alike to the board and to the manufacturer, for the guidance of the chemists of the manufacturer on the one hand, and of the scientific department on the other. These formalities having been complied with to the satisfaction of the board of directors, the manufacturer will then be authorized to print upon the label of each package of each batch of the product that has been approved by the expert or experts in charge or to attach to each such package a separate paster, setting forth the fact that the contents of that unbroken original package have been certified by the bureau under certain rules; and the manufacturer may also print thereon the text of these rules. Each and every such label or paster must bear a number which would indicate, through records to be kept by the bureau, the date of the particular batch and the experts responsible for having approved the standard. At least three times each year two samples of every product bearing the certificate of the bureau will be purchased in open market, in different localities, and submitted to careful examination, in order to determine whether the standard established is being maintained by the manufacturer. If the standard established is not being maintained, the certificate of the bureau will be withdrawn.

Any pharmacist who so desires may become an associate member of the bureau on application, contracting to obey and abide by the rules of the bureau. Rules governing him in the preparation of pharmaceuticals will be, as far as possible, similar to the rules governing the manufacturer, and a system consisting of careful and frequent inspection and check control will be established, as in the case of the manufacturer, in order to protect the bureau certificate. Such associate pharmacists will agree to supply products certified by the bureau, when not otherwise called for, and the physicians will be advised of all associate pharmacists in their immediate vicinity. The bureau will also endeavor to have physicians call for products certified by the bureau, and whenever not absolutely necessary, refrain from specifying particular brands or makes, requiring only that the materials used by the pharmacist shall be of the standards established by the bureau and certified by it.

The members of the joint committee are: American Medical Association—E. Eliot Harris, New York; N. S. Davis, Jr., Chicago; Solomon Solis Cohen, Philadelphia; H. Bert. Ellis, Los Angeles; Philip Mills Jones, San Francisco. American Pharmaceutical Association—H. H. Rusby, New York; Jas. M. Good, St. Louis; C. S. N. Hallberg, Chicago; A. B. Lyons, Detroit; S. A. D. Sheppard, Boston. *Chairman*, joint committee, H. H. Rusby, M.D., New York; *Secretary*, Philip Mills Jones, M.D.

Dr. George M. Edebohls Honored.—At the fifty-eighth commencement of St. John's College, Fordham, held on Wednesday, June 17, the honorary degree of L.L.D. was conferred upon Dr. George M. Edebohls of this city in recognition of his services to medical science.

The Index Medicus.—The first number of this resuscitated publication, that for January, has recently been issued, and it is provided that succeeding numbers will be issued rapidly up to the even date. The subscriptions have not yet reached a sum sufficient, when added to the $10,000 per annum appropriated by the Carnegie Institute, to pay for the cost of publication, and an appeal is made to the profession throughout the world to support the enterprise. The Philadelphia College of Physicians recently adopted a resolution calling upon each of its Fellows to subscribe, if within his power, for at least one copy.

The War on Spitters.—The Board of Health has recently made public an ordinance against spitting on the sidewalks in this city, and tin signs have been placed in certain places, calling attention to the prohibition.

Homœopathy Debarred from the Philadelphia Hospital.—The Mayor of Philadelphia has vetoed the ordinance of councils granting the use of certain wards in the Philadelphia Hospital to graduates in homœopathy.

Smallpox and Typhoid Fever Prevalent in Philadelphia.—For the week ending June 13 there were reported to the Philadelphia Bureau of Health 48 cases of smallpox with 4 deaths, and 238 cases of typhoid fever with 21 deaths. There were also 72 cases of scarlet fever with 2 deaths, and 62 cases of diphtheria with 11 deaths. The total number of deaths for the week was 430, as compared with 427 for the preceding week and 412 for the corresponding week of the previous year.

Dr. William L. Ballenger has been elected professor of otology, rhinology, and laryngology in the College of Physicians and Surgeons, Chicago, to fill the vacancy made by the resignation of Dr. M. R. Brown.

Obituary Notes.—Dr. George P. Andrews, whose death in Honolulu on May 9 was announced recently, was a native of Hawaii, where he was born at Kailua on April 9, 1838. He was educated in arts at the University of Michigan, and graduated in medicine from the College of Physicians in this city. He practised for some time in Detroit, but was obliged, by ill health, to return to Hawaii about fifteen years ago.

Dr. William L. Bradley of New Haven, Conn., died suddenly on June 13, at the age of sixty-six years. He was born in New York City, and was graduated in medicine from the Yale Medical School in 1864.

Dr. Augustin Thompson died in Boston on June 8, from carbuncle. He was born in Union, Me., in 1835, and at the close of the war studied medicine and settled in Lowell, where for thirty years he enjoyed a large practice. He was the inventor of a popular, non-alcoholic beverage, the sale of which brought him in a large income.

Dr. Edward P. Luce died at his home in Bayonne, N. J., on June 5, at the age of seventy-five years. He was a graduate of the Cincinnati College of Medicine and Surgery in 1862, and during the Civil War served as surgeon in the Northern Army.

Dr. John F. Golding of Brooklyn, N. Y., died on June 7, at the age of forty-nine years. He was a graduate of the College of Physicians and Surgeons, New York, in 1875, and had practised medicine in Brooklyn continuously from that date. He was one of a faculty of the Brooklyn College of Pharmacy, and was a member of the Kings County Medical Society and the Kings County Pharmaceutical Society.

Dr. Albert Ferrari was killed recently at Puerto Cortez, Honduras. He had lived for six years in Philadelphia, where he received his medical education, and returned to Honduras only a short time before his death.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

NEW UNIVERSITIES—GENERAL MEDICAL COUNCIL—MULTIPLE SPLENIC ANEURYSMS—SARCOMA OF THE HEART—LEUKÆMIAS—COUNTING THE CORPUSCLES—INFECTED BLANKETS SCANDAL—MORE ANTIVIVISECTIONISTS.

LONDON, May 29, 1903.

YESTERDAY the Privy Council issued draft charters constituting Owens College, Manchester, and University College, Liverpool, separate universities.

Owens College will henceforth bear the title of the Victoria University of Manchester. The sister college will be known as the University of Liverpool, from October, 1903. The Yorkshire College will continue affiliated to the newly organized Manchester University until October, 1904, or until another charter is granted for Yorkshire, whichever event may first occur. Graduates of old Victoria may, for a limited period, select the university to which they will belong.

At the General Medical Council the Pharmacy Bill, now before Parliament, came up for discussion on Saturday. It proposes to prevent any person other than a pharmaceutical chemist from dispensing prescriptions in a "shop," and there is no clause exempting medical practitioners from its provisions. As such a clause is usual, and as pharmacy has always been admitted to be a part of medicine, it would seem as if an attack on the recognized rights of the profession were intended. The act of 1869 had a clause exempting qualified practitioners from its restrictions. The president admitted that this was a very serious interference with the rights of practitioners, though he seemed to think it was a question which the Society of Apothecaries should take up, as it chiefly threatened their licentiates.

Sir V. Horsley held that the whole profession was interested, and pointed out that the British Medical Association had been moving in the matter for the last two months. After some further discussion the president proposed that the Privy Council should be asked to insert in the Pharmacy Bill a clause safeguarding the rights of the profession. This motion was unanimously carried.

The council then considered how the disruption of the Victoria University would affect the constitutions of the council. If new universities should be founded, each might demand to send a representative to the council, which is already too numerous. As to this both a charter and an act of Parliament would be concerned. Birmingham had obtained by act the right to send a representative. Should a petition on the subject be addressed to Parliament? Dr. Mac Vail considered it inexpedient to discuss possible acts of Parliament when so many urgent questions remained before them. In this he was supported by Sir John Tuke, as no bill was at present filed.

Drs. Pye Smith and Paine wished a reduction in the number of members to be urged on the government at the first opportunity, and suggested linking two or three bodies as a mode of effecting the object. Sir C. Nixon opposed and said each body had ideas on medical education and other characteristics. Dr. Windle, representing the new Birmingham University objected to any disfranchisement of the younger bodies. Dr. Norman Moore went further and held that increase of universities would do great good by increasing the public respect for learning. Besides, he thought it a waste of time to discuss the abstract question of the proper size of the council.

Ultimately a vote was taken to decide for or against a reduction of their numbers, when nine voted for, fifteen against, and six did not vote, on which many sarcastically remarked that no one could expect otherwise from the history of the council. Yet the financial difficulties of the body are notorious, and a reduction in its numbers would be one way of increasing its expenditure which probably increasing its efficiency. A memorandum has been submitted to the council on its financial position, which shows that nearly £15.00 per annum is incurred in dealing with penal cases, and suggesting that this amount should be refunded by the government.

These penal cases are not very interesting and a smaller body could deal with them—in fact, it has constantly been remarked that the constitution of the council is scarcely adapted to qualify it for its judicial functions.

Among the cases this year was a rather unusual one. Mr. Henry Varley, a lecturer and writer on "purity," had recommended his doctor to young men whom he desired to rescue from the hands of unqualified quacks. This resulted in the doctor's name and address being lithographed for Mr. Varley to use instead of writing letters, and the publisher of one of Mr. Varley's pamphlets seems to have incorporated this circular without the doctor's permission. The consequence was the doctor had to appear before the council, and after a long defence to find that the facts alleged against him had been proved to the satisfaction of the council, but on his promise to abstain from any such conduct for the future, the council determined not to proceed further. Mr. Varley's pamphlet has been on sale above twenty years, but the doctor's name was not used until a few years ago.

In consequence of the illness of Sir G. Duffey, the council's inspector of final examinations, it was agreed to postpone until next year the inspection of the examinations of the Scottish universities.

Sir Wm. Gairdner has resigned his membership of the council and is succeeded by Prof. N. McCall Anderson. Sir Hector Cameron (also resigned) is succeeded by Dr. Lindsay Steven.

Dr. Trevor showed, at the Pathological Society, a specimen of mutiple aneurysms of the splenic artery associated with calcification and dilatation of the portal, splenic, and mesenteric veins, taken from the body of a man who died of hemorrhage from ulceration of bowel. The aneurysms seemed due to syphilitic degeneration, but other changes suggested Banti's disease, which seemed to have been implanted on the syphilitic soil.

Dr. J. H. Drysdale read an account of a case of primary sarcoma of the heart. The patient was a woman of forty-three years, who died of collapse three days after admission to hospital. It could not be positively said where the growth originated, but, Dr. Drysdale thought, most likely in a large mass in the wall of the right ventricle and septum.

Dr. Parkes Weber read a paper on leukæmias and pseudoleukæmias. He related a case of acute leukæmia which he regarded as a more primitive or a less differentiated type of the chronic forms, but no very distinct line could be drawn between them. Microbic inspection complicated many cases. Splenomedullary leukæmia he considered to be the most highly differentiated form.

A new method of counting the corpuscles, which has been in use for some time at St. Thomas's Hospital, giving results not differing from previous methods, was communicated by Drs. W. M. Strong and C. C. Seligmann. Permanent preparations are made from which both red and white corpuscles can be counted at any period afterward by dilution with appropriate stains and examinations with a one-sixth-inch objective.

No doubt you have heard of the inspected blanket scandal. The newspapers have had enough to say about it. Somebody blundered? Not at all. Routine prevailed. When a regiment returns in peace time, the bedding, etc., is sorted, and that which is becoming worn sold out. So returning from the war, the blankets were sold by routine and after distribution inquisitive officers of health find them infected with typhoid bacilli. Great is the god routine, and the war office is his faithful worshipper. Another sacrifice to him is £150,000 worth of unused army rations burnt in South Africa—while other free rations were being distributed to poor boers. Some one called this wicked waste, but the war office replied the rations were not good. Yet hundreds of people spent days in rescuing from the flames, eating all they could and selling the remainder!

The antivivisectionists have had another field day. Not the society which Stephen Coleridge runs but its rival. They stated that the society for preventing cruelty to animals is about to prosecute the Senate of the London University on account of its administration of the Brown Institute. This will delight the lawyers and the hysterical antis. In seconding a resolution for total suppression, one Dr. Blenkinsopp said: "They would doubtless find ere long that many of the experiments now being performed on animals would most assuredly be repeated on human beings of the poorest class as also on hospital patients, unless some check were placed on the dreadful curse which had found its way here from continental centers."

Mr. Coleridge must look to his laurels.

THE NEW ANGLO-AMERICAN HOSPITAL AT AT CAIRO, EGYPT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: The new Anglo-American Hospital at Cairo is an institution that should be of interest to the profession in America for more reasons than one. It owes its origin equally to English and Americans; it will supply a distinct want to the large class of Americans who spend the winter in Egypt, and it will be so superior in its arrangements that it will merit attention as a model in constructing similar institutions. The number of English and Americans particularly the latter, who spend the winter, or a part of it,

in Egypt, has increased so greatly in the last few years that means for their receiving their proper attention when they have become ill has grown to be a pressing necessity. Everyone knows that a hotel is the last place where a sick person can receive the proper care. During each of the past two seasons there have been over five thousand American visitors to Egypt, and in the natural course of events there must be a certain percentage of illness among such a number of people. There is also a considerable class of British and American permanent residents in Egypt, and of these many are in moderate circumstances. A hospital where one can receive the best care at a reasonable charge is a great boon to people of moderate means in all communities, but especially so in Cairo where, outside such a hospital, proper care and nursing is entirely beyond their reach. Particularly will this hospital come as a blessing to families of small means in event of confinement. The institution, furthermore, is intended to care for the sick of British and American birth who are entirely destitute, so that all cases of all classes will be provided for.

The scheme for such a hospital is not a new one. The necessity for it has been apparent for years, but it was not until two years ago that Sir Ernest Cassell, who financed the Assouan dam and has helped Egypt in so many other ways, made the hospital possible by offering to give five thousand pounds toward its erection. This gave the scheme a great impetus, and under the active patronage of Lord Cromer, the British representative, and Judge Long, the American representative, its consummation was made a certainty. Not only the British and American residents, but many British and Americans who were only visitors in Egypt, subscribed freely toward the scheme. One of the best friends and most valued councillors of the hospital was the late Laurence Turnure of New York. It was through his interest and influence and that of his American colleague on the Executive Committee, Judge Somerville Pinckney Tuck of the International Tribunal, that many American visitors became interested and subscribed liberally, and it was largely due to his wise advocacy that the present site was selected, a site which was undoubtedly the best in Cairo for the purpose. The hospital not only has had wise councillors, but what has been even more fortunate and, what does not always happen, the lay members and the medical members of the Executive Committee, Doctors Keatinge, Sandwith, and Madden of the Kasr-el-Any medical school, have coöperated cordially. The building committee, the architect, the lay and medical members have all worked together, and the results have been highly satisfactory.

The General Committee were particularly fortunate in having for their architect, Colonel Price, Senior Sanitary Engineer of the Egyptian Government, who had built a large number of small hospitals in various parts of Egypt for a government to whom economy was a very important consideration. It is due to this fact that they have been able to build for about thirty-five thousand dollars, two completely fireproof buildings, containing upward of fifty rooms. The main building has about two hundred feet frontage and will accommodate twenty-two patients, twelve of them in private rooms, each private room with a fireplace and veranda, also the administrative and nursing staff, lavatories, store-rooms, operating-room, dispensary, etc. The other building is for kitchen, laundry, and service staff; and in addition to these, there is a small detached mortuary. For less than ten thousand dollars another story can be added on to the wings of the main building, the central part having two stories, and thus double the capacity for patients whenever this should be required. This is truly a surprising result for the amount expended. The building, furthermore, has a handsome appearance and is in a pleasing situation. The present site, which was finally chosen after considerable deliberation, is on the Ghezireh, the island in the Nile facing Cairo. It is on this island that the Khedive Ismail built the beautiful palace which is now a hotel. The hospital occupies a fine open situation, and the surrounding atmosphere is sweet and pure, an assertion that cannot be truthfully made of all quarters of Cairo. Through the further munificence of Sir Ernest Cassell, the site originally purchased has been added to in such a way that the hospital can never be shut in by building operations. The Ghezireh is not much built upon at present, and future building will probably consist of detached villas, so that the situation of the hospital should always be an agreeable one to the most particular patients.

As before said, the hospital provides for patients who cannot pay, for those who can pay a small sum, and for those who can pay liberally, and it is arranged to give this latter class all the comfort and attention they can obtain in the best hospitals in America or Europe, where such patients are received.

The hospital is under the patronage of the King and Queen of England and the President of the United States. The General Committee is under the joint chairmanship of the Earl of Cromer and the Hon. John G. Long. The treasurer is the Hon. Arthur Davy. The General Committee consists of twenty-five members, from whom seven are chosen to constitute an Executive Committee, three of these seven being medical men. The medical staff will consist of English and American physicians, resident and practising in Cairo and the nursing staff will consist of nurses who have been trained in English and American hospitals. The hospital is now finished and will be opened in the early autumn of 1903 to receive patients.

As before said, the building has cost something over thirty-five thousand dollars, the land has cost about sixteen thousand dollars, making a total expenditure of over fifty thousand dollars, all of which has come from private donations. About five thousand dollars is still needed for installation of electric light, furnishings, instruments, etc. As the fees from patients cannot be expected to meet the running expenses, the hospital will require to depend upon the proceeds from the annual "Anglo-American" ball and upon private subscriptions, which the Committee are confident will be forthcoming in sufficient amounts. American visitors to Egypt will be able to take pride in the fact that Americans have done so much to make this worthy institution a success.

C. G. Campbell, M.D.

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE PLAGUE IN MANILA—CHOLERA AND TYPHOID BACILLI IN OYSTERS—CAPT. E. L. MUNSON, ASSISTANT-SURGEON U. S. A., ASSISTANT TO COMMISSIONER OF HEALTH—HEALTH OFFICER FOUND GUILTY OF MISAPPROPRIATION OF FUNDS, AND TWENTY-TWO YEARS' IMPRISONMENT—PRIVATE HERTER OF HOSPITAL CORPS RECEIVES MEDAL OF HONOR.

Manila, April 4, 1903.

There were eighteen cases of bubonic plague, with thirteen deaths, in Manila during the month of February. During the first half of March there were eighteen cases, with a total of forty-three for the month. The disease does not appear to be epidemic, yet it seems to resist every effort to stamp it out and to have secured a foothold in even the best residence districts of the city. To have the disease become epidemic and the port quarantined against it would be a severe blow to the islands, the revenues of which are just beginning to rise again after the wholesale quarantines and interference with trade during the cholera epidemic.

Examination at the government laboratories of oysters taken from the Malabon river has revealed the presence of cholera and typhoid bacilli in these oysters in several instances. Oysters taken from this source have therefore been declared by the Board of Health of Manila to be unfit for food, and their sale in the city has been prohibited. The quality of the Malabon oysters has long been under suspicion, and during the cholera epidemic they have been excluded from the Manila markets.

A large increase of malarial fevers among the troops has led to the publication of a precautionary order looking to the better protection of the soldiers against mosquitos, and the destruction of the latter wherever practicable. Although mosquito bars are furnished to the troops, their proper use has not heretofore been enjoined in orders. An interesting feature of the disease is the statement of an army surgeon who made a microscopical examination of the blood of every man in a native scout company some eighty strong, serving at a post where the white soldiers of the garrison presented a large amount of malarial fevers in hospital. The report says that 19 per cent. of the apparently healthy native Filipino scouts showed malarial parasites in their blood, although presenting no clinical symptoms of the disease. From this it is deduced that the native possesses a certain racial immunity to malaria paroxysms, but may serve as a potent and hitherto unsuspected agent in the transmission of virulent malarial infection to whites, even when the native serving as host shows no outward manifestations of the disease.

There has lately been quite a sharp outbreak of cholera in the Visayan islands of this archipelago, the disease having reappeared in a number of places in which no cases had occurred for some months and which were regarded as no longer infected. In some of the affected towns the deaths from cholera have amounted to from six to ten a day. Several soldiers have been attacked at different garrisons, and sporadic cases occur in Manila from time to time. In several of the provinces of the island of Luzon there seems to be no doubt but that the existence of the disease has been concealed. At present, the cholera mortality, outside of the Moro country, is small, but a considerable number of widely scattered points of infection

still exist, and there is no question but that the beginning of the rains will mark a great increase in the disease throughout the islands. As severe an epidemic as that of last year is not, however, anticipated.

A number of the smaller and more isolated islands, off the usual lines of communication, are now having their first experience with the cholera, which up to now had not gained entrance. The type of disease is severe and the mortality in the villages attacked is very high. As communication between the unimportant villages of the small islands is difficult, the disease has spread but slowly. As regards the sanitary situation of the islands, as a whole, this slowness of spread is unfortunate, as it means that at the onset of the rains, when cholera will find more favorable conditions for its propagation, there will be a large number of small isolated villages in the throes of an acute cholera epidemic—and as the cholera infection has been able to work its way into these little towns, so it will be able to work its way out in the future and reinfect more important cities and islands.

Medical officers in the Moro country report that the great severity of cholera among the Mohammedan natives has been largely due to religious ideas prevailing among them which require that the dejecta be passed into a body of water. In compliance with these ideas, the Moros will frequently go long distances to evacuate the bowels into running water, thus widely disseminating any infectious matter. As a result, all water supplies must be regarded as contaminated, and as drinking water is never boiled by the natives, they are especially prone to acquire diseases of a gastrointestinal nature. As already stated in previous letters, the Moros have largely regarded the cholera epidemic as a wholesale poisoning of them by the Americans, and the feeling of enmity thus aroused has become so acute that a special visit of the Governor and Commanding General to the Sultan of Jolo is planned, with the idea of averting any active hostilities against the Americans.

With the slackening up of cholera, the health officials are seizing the opportunity to perfect their sanitary organization throughout the islands, and have lately divided the archipelago into seven provincial sanitary districts, each in charge of an American medical inspector. The latter are to at once make thorough inspection trips through their districts and study local conditions, so as to render thorough and comprehensive reports to the Board of Health, for use in connection with general health work, and particularly for handling future epidemics. Four of these districts are in the island of Luzon, two in the Visayas islands, and one in Mindanao and the Moro group. Especial attention is to be given by the medical inspectors to general hygienic and sanitary conditions as found; the diseases prevalent in each locality; the average death rate and the principal causes of the mortality; the history of the cholera epidemic; the customs and habits of the people as they have an influence upon health and sanitation; the diseases of live stock, particularly those affecting cattle and carabao. Much attention will be given to the reorganization of health boards and the instruction of local health officials in the proper performance of their duties The carrying out of the above plan will mean much to the future welfare of the islands. The officials of the Civil Government, as a result of the epidemics of plague, cholera, smallpox, surra, and rinderpest, are thoroughly impressed with the fact that industry, commerce, and revenues depend upon health conditions, and have at last come to realize that sanitation is at the foundation of the prosperity of the Archipelago. There is no question but that they have been much worried by the increase in bubonic plague and non-disappearance of cholera, and are willing to do anything the health authorities ask in order to prevent further epidemics. If Manila should be quarantined against, as an unclean port, it would seriously impair the revenues of the insular treasury, already hampered for funds, and would largely prevent the carrying out of the general plan of much needed improvements projected. The importance of sanitation here is fully realized by the members of the commission, who will not be slow to grant the men and money required to secure proper results.

An assistant to the commissioner of health has just been appointed in the person of Capt. E. L. Munson, Assistant Surgeon U. S. Army, who has been relieved from military duty for that purpose. Dr. Munson brings to his new work special qualifications as a sanitarian which will prove of much value in his duties. He is the author of a large work on military hygiene, was for some time assistant professor in that subject in the Army Medical School at Washington, and served several years in the sanitary division of the Surgeon-General's office. At the time of his appointment Dr. Munson was assistant in the office of the Chief Surgeon, where he was acting as sanitary inspector and in charge of sanitary matters. It is understood that in his new position he will act as health officer for Manila.

To further facilitate the sanitary improvements planned to be carried out in Manila in the near future an additional sanitary engineer, at a salary of $3,000, has been appointed to have charge of the work. Heretofore the sanitary engineer for the islands has supervised the municipal sanitary engineering work in Manila.

The trial of the late disbursing officer for the Board of Health, on charges of misappropriation of public funds and the falsification of public documents, has just been concluded. He was found guilty of both charges, and has been sentenced to imprisonment in Bilibid prison for the term of twenty-two years. Such sentences as this have an important sanitary aspect in relation to the expectation of life of white criminals confined for long periods in the tropics. There is no question but that life is much shortened thereby, and that a sentence calling for many years' confinement here places life as well as liberty in jeopardy.

England, France, and Holland all return European prisoners from the tropics to home prisons when they are sentenced to periods of long confinement, the experience of these nations showing that prison life undermines the constitution of white men much more rapidly in the tropics than in the temperate zone, and that but few survive a confinement of as long as fifteen years. It is a serious question whether, in grave cases, receiving less than the death penalty, the courts have a moral right to practically deprive criminals of years of life by condemning them to long imprisonment in the Philippine Islands. There is no doubt but that a twenty-year sentence to be served in Bilibid is a much more severe punishment than the same period to be served in a penitentiary in the United States. It is to be hoped that the authorities will give this matter their serious attention, and take the question of the repatriation to the United States of long-service American criminals under serious consideration. Outside the punishment prescribed in the limits of the sentence, the criminal has as much right to the maintenance of existence as any other man. Such a sentence as has just been given the embezzling board of health employee, to be served out in Manila, is practically a life sentence, even for the young and vigorous, and for this reason is more severe than the crime warranted, and is probably more severe than the judge intended In our occupation of the islands we are gradually learning the fact that our American ideas and customs must be modified to meet local and climatic conditions.

The Manila government has just completed a well-constructed tenement for twenty families on the Tondo waterfront, which is about to be opened to tenants. The rules of the building provide that no chickens or animals can be kept on the premises, cleanliness must be maintained, no stores can be conducted in the building, and the maximum number of occupants allowed for each room cannot be exceeded. The opening of this building, the first of its kind here, marks an interesting experiment in sociology and sanitation. It is doubtful whether good accommodations and low rent will appeal to the Filipino, if to secure them he must sacrifice his game cock, his time-honored filthy habits of living, and his racial desire to herd together in overcrowded quarters.

Private Otto Herter, Hospital Corps, U. S. Army, has just been recommended for a medal of honor for conspicuous gallantry displayed by him in a fight during the past week between a detachment of native scouts with whom he was serving and a large body of entrenched and well-armed ladrones. In this fight over sixty were killed on both sides. The scouts charged an old stone fortification in which the ladrones had taken refuge, and a hand-to-hand fight ensued inside the walls. During the struggle, as it was impossible to attend to the wounded, Private Herter seized a rifle and took part in the engagement. His commanding officers report that he displayed remarkable marksmanship, they bearing witness to the fact that he killed at least six ladrones before having his right arm broken by a rifle ball. After being wounded he drew his revolver with his left hand and continued in the fight, and after the action superintended the first treatment of the wounded, and then walked six miles to receive his own medical attention. His arm is so badly shattered that amputation will be necessary.

Dr. Frederick A. Hesler, U. S. Navy, recently died of liver trouble while on his way to the naval hospital at Yokohama for treatment. Dr. Hesler has been in the Philippines about three years. He was on duty at the naval station at Cavite during the cholera epidemic there, and won much praise for his excellent work among the stricken. Dr. Hesler was a native of Illinois, and was appointed to the navy in 1884, reaching the grade of surgeon in 1898.

HEAVY MODERN MEDICAL BOOKS.

To the Editor of the Medical Record:

Sir: During the past decade the actual weight of the paper used in medical books has so increased that a well illustrated book of to-day weighs any where from one-third more to double the weight of a book of a corresponding number of pages published ten or fifteen years ago. The reason for this is the introduction of the half-tone picture in place of the old-fashioned wood-cut, the half-tone engraving requiring a heavy clay-coated paper for satisfactory reproduction, whereas the wood-cut, like type, may be printed satisfactorily on ordinary unglazed paper. There can be no question but that the modern book illustrated with these half-tone cuts is much more satisfactory and realistic than the old-time book with its crude wood blocks; and the cost of the half-tone engravings in themselves is much less than even very crude wood engravings. But the aggregate cost of producing an edition of medical books to-day is really not much less, if any, than formerly, and if the edition is very large the cost may be even greater, due to the fact that the extra price of the clay-coated paper more than counterbalances the difference in the initial cost of the engravings. But the disadvantage of such books is that they are too heavy to hold comfortably, and the reflected light on the glazed surface of the paper makes the letter press hard to read, particularly by artificial light. If a compromise could be made so that most of the illustrations were printed on glazed paper and most of the letter press on unglazed paper, the finished volume would be far more satisfactory both to hold and to read. That such a compromise is possible and practical is proved every day by such publications as popular books and magazines.

The standard monthly magazines are at present the criterions of excellence in illustrations and letter-press work. If any one will take the trouble to run through almost any one of these he will find that it is made up of two kinds of paper—a glazed paper on which the half-tone and colored pictures are printed, and a "rough" paper on which nothing is printed but the letter press, or at most the so-called "line blocks" made from pen drawings. In a current number of one of these magazines containing 157 pages of printed matter and pictures, I find that 86 pages have clay-coated surfaces, while 71 pages are smooth, non-coated paper. This is so arranged that the coated paper alternates with the non-coated paper so as to give the impression to any one turning through the pages that the pictures printed on coated paper are distributed uniformly throughout the book; but a careful count shows the following arrangement: The 86 glazed pages are distributed in lots of 16, 24, 8, 10, 20, and 8 pages, while sandwiched in between them is the non-coated paper in lots of 7, 18, 7, 14, and 15 pages. By this arrangement nothing is lost in the quality of the reproductions, while the resulting magazine is of a much more convenient weight, cheaper, and much less trying to the eyes of the reader. This difference in weight may not be so apparent in a single magazine, but when the entire twelve issues of the year are bound into one volume the weight is very appreciably lessened.

If the standard magazines, and other standard publications, are justified in resorting to this expedient in the matter of paper there is surely no reason why the same thing may not be done in medical publications. I have before me a medical book of about 1,000 pages, containing about 400 illustrations. Practically all of these illustrations are half-tone reproductions. The paper used throughout the book has the coated clay surface, and the book is too heavy to hold in the hand for any length of time. Of the 400 illustrations I find that 200 are reproduced directly from photographs, which require the coated paper for satisfactory reproduction. Of the remaining 200 about 75 are wash drawings, which, like the photographs, require the coated paper, but the remaining 125 are pen drawings, diagrammatic in character, that could be printed on non-coated paper with equally satisfactory results—in fact, in many instances they would come out better if they had been reproduced direct as line blocks rather than through the half-tone screen. As is the case with almost any book, even when the illustrations, are distributed with great uniformity, as they are in this particular book, I find that the illustrations are grouped closer together on certain consecutive pages with a number of unillustrated printed pages intervening. Even without changing any of the half-tone cuts in this particular book, I find that the printed pages are so arranged that about 350 of light-paper pages could have been substituted for the coated pages without any considerable rearrangement of the cuts. This would have reduced the weight of the book materially reduced the cost, and made the letter press less trying to the readers' eyes. Had the diagrammatic pen drawings been reproduced by the direct, instead of the half-tone, process, the number of coated pages might have been reduced to 500.

It is obvious that in technical medical books it would not be advisable to sacrifice the position of the illustration in its relation to the text to such an extent as may be done consistently in popular books, but nevertheless if the medical writers and medical publishers would have in mind the possibilities of the use of two kinds of paper in the make-up of the book, as magazine editors do, they could save themselves considerable expense and at the same time produce more satisfactory publications. There has been a tendency for the past ten years to reproduce everything photographically, both in popular and in scientific works, and to reject, as far as possible, the diagrammatic pen drawing or wood-cut. This has been overdone, and a reaction has begun in favor of the pen drawing, so long in disrepute, and such drawings are becoming more and more in evidence in the pages of current periodicals. A large number of medical illustrations now reproduced as photographs could be redrawn with the pen to advantage and reproduced as line cuts, just as such illustrations are reproduced in popular publications, The physical discomfort of holding some of the lead-like modern medical books is unpleasant, to say the least, and medical writers and publishers would certainly do well to follow in the footsteps of the publishers of popular books and adopt every measure possible to lighten the weight of their volumes.

Edward H. Williams, M.D.

Progress of Medical Science.

The Boston Medical and Surgical Journal, June 11, 1903.

Dermatomyositis.—F. Forchheimer reports a case of this rare disease. The cardinal symptoms are the following: on the part of the skin, an eruption and sweating; an inflammatory œdema, swollen muscles, painful to the touch and upon motion. The general symptoms are fever and enlarged spleen. The onset of the disease may be very gradual or very sudden, the course may be acute, subacute, or chronic. The skin symptoms in the case reported were erythema, pustules and urticaria, and began about the face, involving the eyelids. The œdema extended over the affected parts and over the abdomen and lower thoracic region. The origin of this affection is not yet fully determined, and if anything at all has been shown as to etiology it is that apparently the disease may be produced by a number of causes. Until these are worked out we can only rely upon symptomatology for diagnosis.

Congenital Inspiratory Stridor.—D. Crosby Greene says that during the past three years five infants have been brought to the Boston Children's Hospital on account of an apparent difficulty in breathing, accompanied by a crowing sound. The diagnosis is based on the following distinctive features: The appearance of the affection at birth; the limitation of the sound to inspiration; the absence of continuous cyanosis; the constancy of the sound independent of the position of the child; the laryngoscopic appearance of the epiglottis and aryepiglottic folds. The prognosis is good. The condition itself is not a direct menace to health, but its presence adds to the danger of any disease of the respiratory tract. One death from laryngeal obstruction due simply to this affection is reported. The treatment is purely prophylactic. It is of great importance that these infants should be properly nourished in order to combat the respiratory diseases to which they are susceptible. Intubation or tracheotomy may be required in very rare cases but in the great majority there is no danger of asphyxiation, and operative interference is hardly to be thought of.

Journal of the American Medical Association, June 13, 1903.

Mercurial Treatment of Syphilis.—M. L. Heidingsfeld advises the injection into the buttocks, or interscapular region, twice weekly, of one to three minims of an ointment made by rubbing together thoroughly equal parts of lanolin and bi-distilled mercury. The latter is the substance employed by dentists for making amalgams. He uses a special syringe (figured in the original article), and the general technique of the injections is that of the modern paraffin injections for the relief of deformities. He claims that the question of mercury in syphilis is merely one of the assimilation of the remedy, and that in the injection method the drug is placed where it will do the greatest amount of good with the least deleterious effect, and that the other natural advantages, in the way of cleanliness, control of patient, accurate dosage, should justly render it the ideal and popular method of treatment.

The Modern Conception of Eczema.—J. A. Fordyce denies that because eczemas follow or are associated with

some general condition, therefore they are directly due to such a state, yet in our search for a local cause of the disease we should by no means minimize the importance of all conditions, both local and general, which favor skin infection. Infectious forms are the more often found in hospital patients in whom cleanliness is not carefully observed, while in the well-to-do, metabolic disturbances may be the major factor. Idiosyncrasy may determine the type of eruption from a given irritant. It is, therefore, impossible with our present knowledge to frame a single hypothesis which will explain in a satisfactory way the clinical group of inflammations commonly classed as eczema. Only a few dermatologists admit the primary influence of pyogenetic and other bacteria in exciting vesicular eczema. It has been shown, however, by several observers that as a result of numerous experiments with the filtered products of bouillon cultures of staphylococcus aureus and albus typical eruptions of vesicular eczema were produced by these investigators, the early lesions of which were found to be sterile. Staphylococci alone gave rise to miliary pustules or other purulent skin affections, but in combination with the filtered chemical products in bouillon cultures eczematous lesions resulted. Eczema is not, then, due to the direct action of these germs, but to the toxin which they secrete. It is this toxin which is slowly generated from the staphylococci usually present in the skin follicles and which, under favorable conditions, permeates the perifollicular tissues that produces the phenomena which are called eczema. The constitutional causes of the disease are the contributing factors which favor the reaction of the skin; the real cause is probably the chemical products of the staphylococci.

The Pathology of Summer Diarrhœas of Children.—G. W. Root makes the following classification of the summer diarrhœas of children: (1) Mucous disease (no pathological change). (2) Diarrhœas of indigestion (catarrhal changes only). (3) Diarrhœas due to food infection (lesions of irritant poisoning, or in slower cases intestinal congestion with punctate hemorrhages in the mucosa; the longest cases present ulcers analogous to those found in typhoid). The lesion varies according to whether the disease results directly from (*a*) preformed poisoning, or (*b*) from the elaboration of poisons within the body. Under the latter class fall the cases of diarrhœas resulting from (*a*) tuberculosis of the bowel, (*b*) typhoid fever, (*c*) amœbic dysentery, (*d*) cholera, (*e*) enterocolitis due to the Shiga bacillus, (*f*) miscellaneous infections. In the class of cases under consideration, the stomach is, as a rule, free from change. The upper part of the small intestine is also usually free from change, but as we pass toward the ileocæcal valve the changes appear. In the mildest cases there is but a moderate congestion. In more severe cases there are points of hemorrhage into the intestinal wall. In cases still a little more severe there are found localized areas of necrosis of the mucosa and submucosa, and if the patient has lived long enough there is ulceration. The mucosa is infiltrated with round cells. Bacilli are found in the tissues of the mucosa and submucosa, rarely deeper. In some cases there is a necrosis of the mucous membrane, as a whole, and a transformation of it into a whitish leather-like substance, which shows no sign of nuclear staining. This layer is sharply differentiated from the inflammatory zone underneath. In cases of less severity the intestinal glands may be found in a state of cystic dilatation. Small hemorrhages are characteristic of this form of infection. In the more chronic cases there is a marked infiltration of the intestinal walls, so that they are thickened and stiffer than normal, while at the same time their lumen is narrowed. The mesenteric lymph glands are usually enlarged.

The Weight Wave of Menstruation.—From a series of observations reaching over twenty-three menstrual periods in four single women between twenty-two and twenty-nine years of age, the following deductions are drawn by W. T. Belfield: (1) During several days, especially the first, preceding the menstrual flow, there occurs a progressive increase in the weight of a healthy young woman, often comprising—especially in winter—from two and one-half to five pounds, which may be from 1½ to 5 per cent. of her usual weight. The climax of this gain is immediately followed by the rapid loss of a large part, perhaps half, of this increase in weight (often within eight to sixteen hours), and then a more gradual loss of the remainder, extending over several days. (2) The menstrual flow begins during the rapid loss of weight mentioned, the appearance of the blood often, though not always, following immediately on the crest of the wave. The flow continues with the less rapid loss of weight during the next few days, terminating about when the woman's weight regains its premenstrual level. (3) The premenstrual gain in weight is due, not to increased ingestion of food, but to diminished excretion, especially of water. The rapid loss of weight following the crest of the wave is due, not to abstinence from food or loss of menstrual blood, but to rapid excretion notably of Co_2 and H_2O. (4) The appearance of the menstrual blood does not always coincide with the beginning of loss in weight; the flow may begin before or, more often, after the loss of weight becomes distinct. (5) After the weight has sunk to its premenstrual level, there may occur another crescendo and diminuendo movement, lasting several days, but less pronounced and typical than the menstrual wave. Hereafter the weight shows no constant variation until there occurs a sudden transient loss, which is the frequent forerunner of the next menstrual wave. (6) A girl of fourteen and a woman of twenty-three, both of irregular menstrual habit, exhibited the menstrual weight wave on several occasions when the flow was nearly or quite lacking. (7) A woman of fifty-nine, who had not menstruated for twelve years, showed no weight wave characteristic of the menstrual period in young women. (8) For two days preceding the climax in weight there is often marked torpidity of the bowels and scantiness of urine; while, with the decline in weight, excretion by bowels and kidneys, as well as by skin and lungs, is notably increased (9) The temperature curve is not constant; there is usually a rise of about 1 F. during the increase in weight and a sudden fall after the crest of the weight wave is passed.

Medical News, June 13, 1903.

Colchicum in the Treatment of Gout.—Charles C. Ransom believes that the varying results in the use of this drug by different observers are due to the different methods employed, and in the want of care exercised in the control of conditions which would materially influence results. The effect of colchicum upon the urinary secretion is at least not to augment it, and in fact, if anything, is rather to diminish it, while the excretion of uric acid and urea under its influence remains practically the same. The writer invariably uses the alkaloid colchicine, which he thinks is the most reliable form, and certainly far pleasanter to take. Various theories have been advanced as to how colchicum acts to relieve and cure gout. As long as we are ignorant of the true nature of gout, we can only speculate as to the *modus operandi* of the drug, and must be content to use it empirically, with such modifications in its administration as a more careful study of its action and a wider clinical experience with its effects may suggest.

Leucoplasia in Secondary Syphilis.—Douglass W. Montgomery says that leucoplasia rarely occurs in the secondary stages of syphilis, but that it does sometimes occur is well known. He reports a case of this kind that came under his observation. The patient was a man of thirty-seven years. He contracted syphilis in August, 1900. About February, 1901, he had a universal rash and sores in the mouth, presumably the first symptoms of constitutional syphilis. The first appearance of the leucoplasia was very insidious, and the date hard to fix, but it was approximately about the middle of the year 1902, or about one year and eight months after the appearance of the chancre. Leucoplasia in general is more frequent in men than in women. But three out of the four cases hitherto reported as arising in secondary syphilis have occurred in women. For the past five months the patient has received 1 or 2 centigrams of bichloride of mercury hypodermically three times a week. The tongue has been swabbed with a ten-per-cent. solution of chromic acid. The persistent mucous patches were scrubbed with a five-per-cent. solution of bichloride of mercury in alcohol. The sublimate was employed only as a necessity, and no further than to secure a healing of the ulcer, because severe mercurial treatment has been taxed, and probably justly, as among the causes of leucoplasia.

New York Medical Journal, June 13, 1903.

Spermaturia.—A. R. Elliott discusses the various pathological conditions under which the seminal fluid may enter the urinary passages and appear as a deposit in the urine. His contention is that this addition of semen will cause the urine to react to several of the ordinary tests for albumin, and will consequently convey a wrong impression unless the control test of the microscope is employed. These seminal compounds show the following test peculiarities: with heat, heat and nitric acid, heat and acetic acid, and heat and acetic acid after previous treatment of the urine with saturated sodium-chloride solution, a distinct, although not heavy albuminous cloud results. Heller's nitric acid contact method yields a faint reaction, much less distinct than that produced by any of the foregoing methods. The potassium ferrocyanide test gives a distinct reaction which is not affected by heat. This reaction does not develop so quickly as with ordinary urinary albumin, but only after a momentary interval, and becomes more pronounced after the test has stood for a few minutes. Moreover, the albuminous cloud does not precipitate in the test-tube on standing, and only

with the greatest difficulty is it thrown down by centrifugal precipitation. The potassio-mercuric-iodide and picric acid tests give plain reactions, which are partially dissolved by heat, to reappear again when the solution becomes cold. The addition of strong acetic acid to the diluted urine yields the mucin reaction, as does also Almén's tannin test used in conjunction with saturated salt-solution.

Do Our Present Ways of Living Tend to the Increase of Certain Forms of Nervous and Mental Disorder?—C. E. Atwood answers this question in the affirmative. Much of the neurasthenia of the present time results from autoinfection caused by incomplete oxidation of the exhausted tissue cells, leucocytes, etc. These semioxidized materials are extremely toxic, and anything allowing of their accumulation in the system becomes a menace, especially to those who are by heredity of a nervous disposition. In addition to modern hurry the increased consumption of alcohol is a cause of nervous disease. Acting in a similar way are over-eating and over-drinking of non-alcoholic beverages, habits which tend to develop arteriosclerosis and to cause apoplexies at an earlier age than formerly. Still another factor is the effect of the immigration of inferior foreign types into this country. Upon an investigation of the facts in the case regarding the insane in the New York State hospitals in a recent year who were of foreign birth and foreign parentage, the author found that outside New York City 50 per cent. had parents of foreign birth, and 30 per cent. were themselves foreign born. In New York City 78.32 per cent. of all cases admitted to the City Asylum had parents of foreign birth, and 67 per cent. were themselves foreign born. At the Vanderbilt Clinic, in the year 1902, 80 per cent. of the cases of neurasthenia belonged to our foreign population, Russian Jews predominating. The causes of insanity and neurasthenia in these immigrants were chiefly faulty heredity, poverty and attendant evils, physical stresses, emotional excitement, intemperance and sexual excesses.

American Medicine, June 13, 1903.

The Effect of Altitude upon Pneumonia.—F. Gregory Connell gives statistics of the mortality of this disease at an altitude of 10,200 feet. The total death rate was 26.4 per cent. in 261 cases. Comparison with statistics of regions at or near sea-level would suggest that altitude has but little, if any, influence or significance in the mortality rate of pneumonia. Nor would it seem that altitude has any influence upon the etiology, the prognosis, or the treatment of this disease. Exposure and alcoholism seem to be the usual causes at a high elevation and at a low one, when a cause can be discovered or suspected. Newcomers to the altitude mentioned above do not seem to be more prone than are the older inhabitants to contract pneumonia. As to prognosis, it is just as uncertain at the elevation of 10,000 feet as at sea-level. The writer hopes to help to remove the idea, an erroneous one, he believes, which is not confined to the laity, that pneumonia is a more dangerous disease at high elevations than it is at sea-level.

Fourth-of-July Tetanus.—H. Gideon Wells declares that every case of blank-cartridge wound should be considered from the start as a dangerous emergency, and should be treated with the same thoroughness that would be indicated if it were known positively that tetanus bacilli were in the bottom of the wound. If possible, the patient should be anæsthetized, and this is almost necessary in injuries of the palm. The wound should be thoroughly cleansed on general surgical principles, especial care being taken to remove all contused tissue, not to mention foreign bodies. The entire surface of the wound should be cauterized, best with the actual cautery, and then packed in such a manner as to ensure that no dead pockets can possibly exist, and that healing will take place from the bottom. After the tetanus has once developed, its treatment is much the same whatever the original cause. Radical cleansing of the wound, with removal of the adjacent tissues, best supplemented by the actual cautery, is essential. The use of antitoxin is to be urged in every case of tetanus. Prohibition of the sale and use of explosives, at least those that produce solely the effect of noise, is the proper solution of the troubles of the Fourth, and making their sale illegal would have a decided effect on the day's events, even if complete prohibition could not be accomplished.

Philadelphia Medical Journal, June 13, 1903.

The Present Status of the Treatment of Superficial Carcinoma and Tuberculosis by Means of the X-Rays.—William L. Rodman and G. E. Pfahler conclude that: The length of time required for the cure of epitheliomata is longer than by surgical or caustic treatment, while the cosmetic results are better. The dangers are proportionate to the urgency of the treatment, as indicated by the degree of malignancy. It should only be recommended in cases that are inoperable either because of the extent of the growth or its location. It is absolutely the best means at our command for the treatment of superficial tuberculosis, and it gives better cosmetic results. It should follow all operations for malignant disease or tuberculosis, with the twofold object of stimulating the healing process and of preventing a recurrence. In some cases it may be of advantage to give a course of treatment before operation, to destroy the outlying portions of the growth and make such operation of a less formidable nature.

The Value of Widal's and Ehrlich's Tests in Typhoid Fever.—Orville A. Kennedy declares that the Widal agglutination test furnishes the earliest and most positive evidence of typhoid fever. The diazo-reaction, although not pathognomonic nor as conclusive as the agglutination test, is a valuable aid in making an early diagnosis of typhoid fever. Its presence differentiates between malaria and typhoid, and practically eliminates all but measles, acute miliary tuberculosis, and probably certain septic fevers. Measles may be easily excluded. Acute miliary tuberculosis produces the reaction only in severe cases and late in the disease, when other symptoms clear up the diagnosis. Possibly septic fevers may cause some uncertainty if the focal point of the septic process is not clearly manifest. The reaction may be present on the fourth day, and may be continuously or intermittently present throughout the disease, or disappear early. Its disappearance is favorable. To obtain its full value, tri-daily tests should be made throughout the disease. This will be of value both in confirming the diagnosis and as an index of the progress of the disease.

Immunization against Tuberculosis.—D. E. Salmon reviews the work on this subject and refers to a paragraph in a recent article by Flexner of Philadelphia, beginning as follows: "To whom belongs the credit of protective inoculation against tuberculosis?" He proceeds to speak of the work of Theobald Smith and of Trudeau. Salmon calls attention to the work of Behring, and Pearson, and Gilliland. They have produced immunity in cattle by inoculating them with varieties of tubercle bacilli of human origin, the virulence of which was not sufficient to produce appreciable pathological lesions in bovine animals. Again, de Schweinitz, in the laboratory of the Bureau of Animal Industry, demonstrated that he had obtained an attenuated bacillus, produced immunity in guinea-pigs and proved its harmlessness for cattle two years before Smith pointed out the differences between bacilli from the nasua and those of bovine origin. Trudeau freely conceded that de Schweinitz was the first to call attention to de Schweinitz's results in protecting guinea-pigs by means of living attenuated cultures, and that his own (Trudeau's) results were not as good as those of de Schweinitz. Daremberg, in 1889, made experiments looking to the production of immunity by inoculating guinea-pigs and rabbits with sterilized cultures of the tubercle bacillus. Grancher and Martin in the same year presented a paper showing that they had discovered a reliable method of attenuating the tubercle bacillus. The writer then reviews the work of Trudeau, de Schweinitz, and Theobald Smith. The writer concludes by calling attention to the work of de Schweinitz, saying that he had discovered that certain human tubercle bacilli might be administered to cattle subcutaneously, intravenously, and intra-abdominally without producing disease, and had so administered them with the view of producing immunity in cattle before Smith's papers were published. How can it be said, therefore, that these later papers were an "essential prerequisite" to such studies? Possibly there are more American investigators who have accomplished results in the field of medical research than is realized even by some of our own writers on the subject.

The Lancet, June 6, 1903.

Soil Nitrification as Affecting Malaria and Other Mosquito-borne Diseases.—A. R. Waddell was led to the studies on which his paper is based by noting the deadly effect of attenuated ammonia solution on mosquito larvæ. He believes that the nitrogen of the soil (increased by certain agricultural methods), plays an important rôle in this respect. He attributes the decrease of malaria in England during recent years, not merely to improved drainage, but to an increased nitrogenization of the soil by the increased use of phosphate manures, its extended growth of clovers which add to the nitrogen in the soil and the enormously increased use of nitrogenous fertilizers. The same principle applies to and explains the diminution of certain parasitic diseases in cattle.

A Case of Typhoid Pancreatitis.—The patient of B. G. A. Moynihan was a boy of thirteen years who had recovered

from typhoid fever but complained of severe epigastric pain coming on in attacks with nausea, rarely vomiting and later, jaundice. No febrile reaction was present. Emaciation was considerable. A diagnosis was made of typhoid infection of the gall-bladder, with the probable formation of gallstones and the impaction of one in the common duct. Abdominal section revealed the cause of the jaundice to lie in the pancreas. The head and much of the body of the pancreas were found to be at least twice as large as the normal and almost as hard as stone. The common duct was buried in a mass of densely hard inflammatory material in the head of the pancreas. The gall-bladder was aspirated and about half an ounce of bile was withdrawn into a sterilized vessel. A drainage-tube was sutured into the gall-bladder and the abdominal wound was closed in the usual way. Recovery was uninterrupted.

A Form of Removable Deep Suture.—The method is described in full by F. R. S. Milton, and must be read in the original by those interested, and is based on the application of the familiar "lock" stitch of the modern sewing machine, in which the efficiency and neatness of the stitching depend upon preserving the ratio between the tensions of the two threads employed. If the tension is properly regulated the interlocking of the threads will take place in the substance of the material under suture, whereas if the tension of one of the threads be greater than that of the other the interlocking of the threads will take place on the surface of the material and on the side of the thread with the highest tension. By using two threads with different pliability in surgical suturing the same effect can be produced as would be caused by extreme difference in the tension in machining; thus, if one thread be of silk and the other of, say, stiff steel wire, it is obvious that instead of the threads interlocking in the substance of the material they will hardly interlock at all, but the more pliable silk will simply pass round the stiff wire and the turns will be all on the side of the material to which the wire is applied, and, further, it will be found that on pulling the wire this can be easily withdrawn, and in consequence the silk, having lost its support, can also be withdrawn with the slightest pull.

The Relation Existing between Uric-acid Excretion and the Breaking Down of the White Corpuscles.—Elaborate tables based on a study of eleven cases are given by O. K. Williamson. Commenting on the statement of Kühnan that, with the increased excretion of uric acid there is a fall in the leucocyte curve, he shows that the result may be referable, not to an increased destruction of leucocytes, but simply to a diminished production of them. From an examination of his tables it will be seen that in seventeen out of twenty instances in which an increased excretion of phosphoric acid follows a fall in the white blood-corpuscles curve, pointing to an increased destruction of white corpuscles, there is associated with this increase a corresponding increase in the amount of uric-acid excreted. In thirteen instances there is confirmatory evidence of increased destruction of the white cells obtained from the differential counts, whilst in three instances this confirmation, owing to the absence of differential counts, could not be obtained. In five instances the examination of the differential counts gave a directly opposite interpretation to the study of the white corpuscle and phosphoric-acid curves, the one pointing to increased destruction and the other not. Most of the observations were on cases of advanced pulmonary tuberculosis. If the curves are carefully examined it is seen that in those cases in which there are great and sudden variations in the number of white cells, there are also great and sudden variations in the amounts of uric acid and phosphoric acid excreted. This tends to confirm the theory that uric acid is derived from the white corpuscles. It will also be observed that in the case of three children, whose histories are given, there is, relatively to the body-weight, more uric acid and phosphoric acid excreted than in the case of adults. This may be explained by assuming a more rapid destruction of the white cells in the former case than in the latter.

British Medical Journal, June 6, 1903.

Tuberculosis of the Conjunctiva Cured by X-Rays.—Sydney Stephenson reports the case of a child of four years who came for treatment of tuberculosis of the conjunctiva. The affected part was treated by exposure to the *x*-rays at a distance of 6 to 10 inches from the focus tube for an average period of ten minutes at each sitting. The only other treatment consisted in bathing the eye three times with 1 in 5,000 sublimate lotion, and cod-liver oil and steel wine internally. The diagnosis of the case could not be questioned, as the bacilli were proved to be present. There is no visible cicatrization from the treatment, and the cure is complete. The treatment by *x*-rays is simple, painless, and free from danger, and it is likely in the future to displace the other methods of treating tuberculosis of the conjunctiva.

Further Work on Amœbic Dysentery in India.—Leonard Rogers concludes that (1) Amœbic dysentary is most frequently found in patients dying from large, tropical liver abscess, in the walls of which amœbæ can always be found, unless they have been opened for some time. The disease is chronic, and often latent, and not very often fatal by itself, but usually through complications. (2) Amœbic dysentery has naked-eye and microscopical characters which enable it to be easily distinguished from the more common bacillary type of the disease. (3) Its most important complications are large abscess of the liver, chronic or acute peritonitis, and post-peritoneal abscess. (4) Amœbic abscess of the liver secondary to this form of dysentery may be produced by infection across the peritoneum, with or without previous adhesions; or, through infection by the portal vein, producing sufficient clotting in its branches to cause a focal necrosis in one or more part so the liver, concentric extension taking place by means of a similar process. (5) If staphylococci reach the liver with the amœbæ, as especially occurs when gangrenous sloughing of the bowel wall complicates amœbic dysentery, then multiple small abscesses in the interlobular staphylococci result. (6) The bacillary form of dysentery is much commoner in Calcutta than the amœbic one, and is due to Shiga's bacillus, which is clumped by the blood of cases of ordinary dysentery, although not by that of the amœbic form, this furnishing a method of differentiation between them clinically.

Remarks on the Red-Light Treatment of Smallpox; Is the Treatment of Smallpox Patients in Broad Daylight Warrantable?—Neils R. Finsen states as an irrefutable fact that daylight, and especially the chemical rays, have a most injurious effect on the course of smallpox, as the suppuration of the vesicles is due to the effect of the light. It is possible to avoid suppuration, and its consequences, by protecting the patients from the action of light. The greatest number of deaths are due to suppuration. The action of light on the course of smallpox is astonishing, and the effect of the red-light treatment is one of the most striking results known in medicine. Even in cases of confluent smallpox, or in unvaccinated persons, the method very rarely fails, if the treatment is begun early enough. If suppuration has begun, or is on the point of beginning, the red-light treatment will not stop it It is now ten years since the writer proposed this treatment. This is not, properly speaking, medical treatment; it is more a preventative measure against the injurious effect of light. When a disease in question is one in which the public health authorities oblige the patient to go into a particular hospital, he has a right to ask that he shall not there be unnecessarily exposed to dangers that may be fatal, or, at least, are liable to disfigure him for life. It is absolutely unwarrantable on the part of the public health authorities to treat serious cases of smallpox, in which suppuration might be expected, in hospitals where patients are exposed to daylight. The incompetency shown by the physician who allows the patient to lie in daylight is no less stupendous than if he neglected the ordinary aseptic measures in performing a capital operation. The disease has proved to be of much shorter duration when the redlight treatment has been carefully adopted. Some authors think even the danger of infection is lessened when suppuration is prevented.

Deutsche medicinische Wochenschrift, May 21, 1903.

Tuberculosis of the Lymphatic System.—Eduard Hitschmann and Oskar Stross report a case of pseudoleukæmia which presented all the typical symptoms and which terminated fatally after about one and a quarter years' duration. Upon autopsy the enlarged lymphatic glands, liver and spleen, as also the kidneys, were found to contain numerous histological tuberculous lesions, together with a fair number of tubercle bacilli. Clinically, the case was one of febrile pseudoleukæmia, such as have been described by Sternberg and others, who have held that the condition was tuberculous in origin. The present case confirms these views.

Berliner klinische Wochenschrift, May 25, 1903.

Anti-morphine Serum.—J. Morgenroth has been unable to produce an anti-morphine scrum by the inoculation of ascending doses of morphine hydrochlorate into rabbits, goats, or dogs. It is true that at times mice which have been treated with such a serum do not succumb to the usual fatal dose of morphine, but the same holds true when the mice have been previously inoculated with merely *normal* rabbit serum. It is therefore extremely probable that Hirchlaff's results were deceptive, and that the apparent protection of his mice was merely an accidental occurrence. It is at least certain that his maximum fatal dose (.01) of morphine for mice is too small, and that the amount should be at the lowest .0165 gm.

Bodily Exercise and Alcohol.—Ferdinand Hueppe says that with the proper regulation of bodily exercise in the gymnasium and the various branches of athletics the use of alcohol is entirely superfluous, and that entire abstinence from alcoholic beverages is to be recommended during the continuation of "training" and in conjunction with all forms of bodily exercise and physical culture.

Münchener medicinische Wochenschrift, May 26, 1903.

Obstetric Rarities.—Hildebrandt reports two cases. The first was a laceration of the symphysis pubis during a forceps delivery. The case pursued a favorable course and entirely recovered in six or seven weeks. The second was a case of vagitus intrauterinus. There was a prolapsed cord. This was replaced and forceps applied. During the latter procedure the child gave a pronounced cry. Delivery was accelerated and a highly asphyxiated child extracted. The latter, however, responded well to the usual treatment.

Prolonged Lactation.—Nussbaum reports two cases in which lactation was prolonged for from one and a half to two years after weaning, although repeated attempts had been made to suppress the flow of milk. The patients were suffering from severe anæmia. When the cases came under the care of the author they were at once placed upon .5 gr. of antipyrin four times a day, together with mild cathartics. A breast binder was also applied. This treatment was soon followed by a complete cessation of lactation.

Immediate Delivery Is the Best Treatment of Eclampsia.—E. Bumm, from an experience with twenty-five cases of eclampsia during the last two years, advises the immediate evacuation of the uterus in all cases of eclampsia. By this course the mortality may be greatly reduced in all cases in which after the first attack the pulse is good and the lungs are intact. Of the twenty-five cases here reported three died. Delivery was accomplished in the following manner: 1 by Cæsarean section, 7 by hysterectomy, 7 by forceps, 6 by podalic version, 1 by podalic extraction, and 3 by craniotomy.

The American Journal of the Medical Sciences, June, 1903.

A Case of Gangrene of the Lung Cured by Operation.—David Riesman, A. C. Wood, and G. E. Pfahler report a case of this nature. The patient was a negro of sixty-three years. The *x*-ray was used as an aid in locating the pulmonary lesion. The skiagraph confirmed the physical signs. At the operation the fifth rib was exposed by a slightly curved incision, an inch and a half or two inches being restricted by the subperiosteal method. The gangrenous part of the lung was just beneath the pleura. The walls of the cavity were gently cleansed by gauze sponges, and the cavity was then packed with sterile gauze, and the usual dressings applied. The second radiograph of the case showed a restored lung. Whether there was a true hyperplasia of air besides, or merely an enlargement of existing ones, it is not possible to say without other, especially experimental, data.

The Dermatoses Occurring in Exophthalmic Goiter.—James Nevins Hyde and Ernest L. McEwen declare that it is clear that important lesions of the skin, some involving serious structural change in the corium and subcutaneous tissue, may coexist with exophthalmic goiter. About one hundred and eleven reports have been made of cases of this character. The list including, first, about forty-nine cases of hyperidrosis; next, each in equal frequency, fifteen of pigmentary changes and myxœdema; about fourteen cases of simple œdema of the skin; five cases of scleroderma, most of them generalized, a small portion representing the circumscribed form; then alopecia, often generalized, and vitiligo; lastly, one or two instances each of telangiectasis, purpura, urticaria, erythema, and one only of hidrocystoma, reported in this paper by the authors. Among the accidents of the same morbid process, most of them evidently rare, are hemorrhage from the skin, bronzing of the integument, eczematous and erysipelatous accidents and localized anæsthesia.

Zomotherapy in Tuberculosis.—Lawrason Brown concludes: (1) That raw meat has no perceptible effect on the duration of experimental tuberculosis in dogs, if the bacilli are virulent, and a sufficient number injected intravenously. (2) That raw meat has no effect on the prolongation of the duration of experimental tuberculosis in dogs, even if the bacilli are attenuated, provided a reasonable quantity be injected intravenously. (3) That under the same conditions, dogs fed on a mixed diet with no raw meat may live a much longer time. As to the use of meat in pulmonary tuberculosis, it may be said: (1) That meat is highly essential in the dietetic treatment. (2) That much meat with a judicious admixture of carbohydrates, fats, etc., is essential to the treatment. (3) That rare meat is better than meat well cooked. (4) That meat-juice is of great value in suralimentation, as myosin albumin is easily digested by most patients—even the dyspeptic, and it affords a "maximum of nutrient for a minimum of effort." (5) That meat-juice can be taken when patients can take no other form of meat. (6) That the juice from raw meat seems slightly, if at all, more beneficial than the juice from meat slightly browned. (7) That the disadvantages of preserving and preparing raw meat-juice more than offset its advantages. (8) That meat-juice is of value, as it can be administered in the form of jellies, ices, etc.

The Blood-pressure Reaction of Acute Cerebral Compression, Illustrated by Cases of Intracranial Hemorrhage.—Harvey Cushing, in summarizing his paper, draws attention to the following points: Varying degrees of rapid increase in intracranial tension produce corresponding disturbances in the intracranial circulation. To these circulatory disturbances the symptoms of compression are solely due. The condition known as acute cerebral compression may be conveniently subdivided into four stages, dependent upon the degree of circulatory alteration which has been reached. Each of the stages has its own more or less characteristic symptom-complex. The major or underlying symptoms originate in the centers situated in the medulla, and are only called out when the degree of intracranial tension begins to approach the arterial tension, so that anæmia is threatened. A circulatory condition in the medulla which borders upon anæmia has the effect of stimulating the vasomotor center. Thus, a rise in blood-pressure is occasioned, which restores the local circulation. The extent of this rise may be taken as an indication of the degree of advancement of the compression. Beyond a certain point, however, this reaction cannot take place. The vasomotor center under these circumstances fails, and the respiratory efforts cease entirely. In conjunction with other symptoms, a progressive increase in arterial pressure or a high degree of the same, which has been already reached, or a pressure which exhibits from moment to moment great alterations in level may be taken as a certain indication of the advisability of early operative intervention. In case there are localizable symptoms the site of trepanation is plainly indicated. In case of generalized compression from widespread hemorrhage there are no localizing indications, the intracranial tension should be relieved by the elevation of a large osteoplastic flap from one hemisphere or the other, with a corresponding opening in the dura.

A Case of Myelogenous Leukæmia with Several Unusual Features (Absence of Eosinophilic Leucocytes).—Charles E. Simon reports a case of this kind. The patient was a man aged forty-two years. He became markedly anæmic while under general observation without apparent cause, and, barring a brief interval during which he seemed to have gained some ground, steadily declined in health, and died at the expiration of seventeen months from the time at which the anæmia was first noted. Subjectively the patient presented no symptoms until well along in the course of the disease, and then he merely complained of shortness of breath on exertion, and a gradually increasing, though not very pronounced, general weakness. Objectively there was a very moderate enlargement of the spleen, which only appeared after several months and then slowly increased, but which became quite extensive toward the end. There was very little glandular enlargement, if any, until quite late in the course of the disease. The oligochromæmia was quite intense from the beginning and out of proportion to the diminution of the red cells. At first there was no hyperleucocytosis. Later a moderate increase beyond the physiological maximum occurred, but toward the end, this increase reached very extensive proportions, the ratio of whites to reds falling to 1 to 16.6. Neutrophilic myelocytes were present from the beginning in notable numbers. They steadily increased until shortly before the end, when they diminished again, but even then did not fall below 25 per cent. There was a corresponding diminution in the number of polymorphonuclear neutrophiles and at the same time of the small mononuclear elements. Large monocular elements, which were not present in notable numbers during the greater course of the disease, became more numerous and finally constituted 54.8 per cent. of all leucocytes. Mast cells were at first absent, later they appeared, and with some fluctuations they steadily increased until the end. Of eosinophiles only two cells were found in the course of all the examinations, one of which was an eosinophilic myelocyte. Neucleated red cells, both of the normoblastic and megaloblastic variety, were present throughout the course of the disease, but notably much more numerous in the early stages. Toward the end but few were seen.

Society Reports.

NEW YORK PSYCHIATRICAL SOCIETY.

Stated Meeting, Held April 1, 1903.

ALLAN MCLANE HAMILTON, M.D., IN THE CHAIR.

The paper of the evening was read by Dr. ALLAN MCLANE HAMILTON (see page 965.)

Dr. WILLIAM HIRSCH said that all cases of juvenile insanity, which gave rise to manifestations of crime, would offer little difficulty as to diagnosis if they belonged to one of the well-known categories of mental disease, such as paranoiac, epileptic, etc. If, on the other hand, they had to deal with cases without any delusions or other psychopathic symptoms except the morbid impulses leading to the commitment of crimes, as in the case related by the President in his paper, in which a boy became a murderer as the result of a morbid propensity to murder, without any direct delusions, then it might become extremely difficult to prove insanity, and to distinguish such a case from ordinary viciousness by establishing a mental disease, such as was necessary for legal purposes.

He stated that there had been one pertinent question raised in connection with these cases, and he thought it would be well for this society to take a direct standpoint regarding it; that was, whether these cases of so-called moral insanity were merely characterized by morbid impulses leading to crimes of various kinds, or whether they must always have a defect in the intellectual capacity in order to prove insanity. This question had repeatedly been made the subject of discussion. A great many authors held that moral insanity did not exist, except as a symptomatic feature of general imbecility, or a morbid development of the entire psychical organ. On the other hand, there were men who claimed that it was not necessary for moral insanity to be associated with intellectual weakness. He said that a boy might be well developed intellectually, and still possess morbid impulses to steal or kill. In other words, manias like kleptomania, or mania to murder, could occur in individuals who, intellectually, were normally developed. Both these views had their representatives among psychiatrists. He said that if he understood the President correctly, those causes which he reported showed intellectual weakness at the same time.

Dr. Hamilton answered in the affirmative. He did not believe they would be considered by psychiatrists as ordinary cases of imbecility. That was a post-natal defect due to gross disease. He said he did not believe in an inherent moral weakness without mental power, and that there should be enough mentality developed for selection or comparison. He did not believe in pure imbeciles without ideas; there must be some mind.

Dr. Hirsch said that these two views, one claiming a co-existing intellectual weakness, the other not, had followers who carried their beliefs to the extreme. There were undoubtedly a great many cases which stood on the border line, and where it was difficult to decide whether the morbid propensities were accompanied by a marked under-development of the intellectual capacity. Those cases which had come under his personal observation were always of such a nature that he could not consider them normal apart from their morbid impulses to steal or kill. There were always a large number of psychopathic conditions besides, and especially a marked defect in their ability to form logical deductions and conclusions. He said that it was true that some of these boys showed quite well developed intellectual abilities, and even manifested special talent, such as writing or speech-making, talent for art or music, etc. But they all lacked the ability to draw logical deductions and conclusions. Their intellectual brilliancy was only a seeming one, their defect manifesting itself in any attempt of logical discussion. He related the instance of one boy who had an irresistible impulse to steal, which would surely have led him into state's prison had he not been taken care of; this boy had a decided talent for mathematics. He was, in fact, an excellent mathematician. His intellectual capacity had developed in this one direction only. When the doctor examined the boy he was struck regarding his inability to draw logical conclusions or deductions regarding any other subject, even of very simple kinds. It was impossible to have any logical discussion with him. He would argue in somewhat the same way as did the boy mentioned in the President's paper, who wanted to kill his mother: "I want to kill her because I do not like her." This question as to the presence of other psychopathic symptoms outside of morbid impulses, and especially as to intellectual weakness as a necessary element of moral insanity, seemed to him of special importance regarding expert testimony. A symptom which was present in nearly every case of moral insanity was that of lying. Here they had to distinguish between various forms: First, there was the ordinary lying with a motive, either to hide his crime and escape punishment, or to brag about his accomplishments. As a rule, these lies bore the stamp of weak-mindedness. A little girl, for instance, who possessed a number of morbid propensities, was not promoted in school. She came home and lied to her mother, saying that she had been promoted, in spite of the fact that her mother was bound to find out the untruth within a short time. Another form of lying was that without any motive. Children with moral defects often seem to lie merely for the sake of lying without any advantage to themselves. Finally, he said, they had the symptom of "pseudologia phantastica," when children relate whole stories for which there was no foundation, but in which they themselves firmly believed. Such children were unable to distinguish between real events and the products of their morbid imagination. A striking example for this symptom was furnished by a recent case. "Hooper Young" constantly told such stories without any advantage to himself, firmly believing in their reality. Once he told a friend that his mother had died and related her death with all its details.

Dr. H. E. ALLISON, Medical Superintendent Matteawan State Hospital, said that they had not had much experience with infantile forms of insanity, because the youngest cases that usually came under their observation were not less than from sixteen to twenty years of age. Undoubtedly, however, a great many children of the class referred to in the paper were mentally deranged.

Dr. Hamilton asked what was the history of those people he came in contact with.

Dr. Allison answered that some must have been insane in childhood because when they came to them in future life they presented histories showing that in early youth they had been a continual source of trouble and care. They showed evidences of a lack of mental development. Unavailing efforts had been made to provide for them by placing them in special institutions or with special attendants, or by sending them to sea. The history of such young individuals often showed criminal tendencies and a lack of moral and mental development. The parents of such boys often expressed themselves as being well pleased when they were placed in their care, because the parents felt that such youths would be held in safe custody without having the stigma of conviction attached to them. Experience showed that when these boys were committed to institutions for the care of children they will run away and become truants. They cannot be kept among the other children by means of ordinary restraint. If they do remain, they are inclined to demoralize the school. Their natural proclivities are to injure or to torment others and appropriate or destroy property. At the Matteawan State Hospital the majority of these inmates presented physical abnormalities or mental deficiencies. Many were imbeciles but not idiots. The latter might be found at

Syracuse or Rome. Such imbeciles, upon admission, usually presented physical defects, the result of pre-natal influences, or indications that in infancy they must have suffered from encephalitis, cerebral hemorrhages, or affections of the nervous system, resulting in paralysis and atrophic conditions of the body. These cases might show defects in the formation of the teeth or palate, or present other stigmata of degeneracy. Such patients offered no hope of cure and but little encouragement for improvement. They also had some cases of apparent intelligence who were, nevertheless, governed by obsessions, impulses to do wrong, ungoverned desire to make assaults, to kindle fires, or to destroy property. These cases could be taught to exercise a great deal of self-restraint. Unless they cultivated such an exercise, they were classified as *disturbers* and placed in violent wards where attempts to annoy or assault were at once forcibly resented by other patients. Nothing so quickly taught self-control as such an experience. A habit of disciplining their impulses was soon self-imposed.

They had received some youthful pyromaniacs. One youth in particular was very intelligent. Physically and mentally he seemed well constituted. He could not, however, control the desire of starting fires until he was placed under the restraint of an institution. The ringing of a fire bell would set him in a tremor; a moving picture exhibition in which one of the photographs represented a fire engine in action greatly excited him and rendered him sleepless, and disturbed for days. A colored puzzle picture, published in a newspaper, showing some sulphur matches, came to his notice, which illustration he cut out and carried in his vest pocket, deriving a kind of morbid pleasure from viewing it occasionally. It was such a source of temptation, however, that he finally gave it up, asking that it be destroyed, as he feared that he might yield to the temptation and burn the institution. Such pyromaniacs usually presented evidence of some mental affection; but this case did not offer many active symptoms beyond mental depression, produced apparently by feelings of repentance and remorse at the enormity of the crime which he felt continually impelled to commit.

There was a certain other class of juvenile cases that came to them. They might find, for instance, that the discipline of an institution had been upset by one person and a state of terrorism might have been thus produced by one or two inmates. These cases were not always insane, but the love of excitement and notoriety, or some other vain impulse, might have inspired the acts which they had committed and in which they took pride as leaders. Occasionally such a person was committed to their custody and discharged as not insane.

Other commitments were made to the hospital of persons who were kleptomaniacs. Their parents or friends did not think they were fit subjects for prison, and really they were not. They simply could not resist the impulse to steal, usually appropriating useless articles, and had only been kept from prison through the influence of friends. Such young persons often make good recoveries. He recalled the case of one boy who followed this propensity to steal for years, and even continued the practice while in their custody. During the five years spent with them, he gradually gained self-control enough to relinquish the habit, and was discharged. For two or three years he had followed the occupation of stenographer, and had apparently recovered.

The question of insanity in many of these cases was difficult to decide. Some were really on the border-line. They did not believe that the prison was the place for all such juvenile offenders. Some of them with benefit could be placed in a good school with strict disciplinary features or placed in charge of persons who would have a proper corrective influence over them. Others, older in years, if not insane, might be so incorrigible as to require the less hopeful but more stringent remedy of a commitment to a penal or corrective institution. If mentally deranged, however, they should be committed to an asylum, there to remain until they were no longer dangerous to be at large.

Whenever these degenerates had been sentenced to a term of imprisonment and thereafter found to be insane while undergoing sentence, they were committed to their custody. After the expiration of their terms of imprisonment, if they were reasonably safe to be at large, the law permitted their parents, guardians, or friends to assume their custody, if they were able to provide for them. In such cases they were often asked to release them on trial. Their after-history frequently proved that such boys were likely to return to their former habits and again become the cause of anxiety to their friends and a nuisance in the community. They had been asked in such cases to receive them again into their care; but in the absence of any criminal act committed by them there was no legal way by which such re-commitments could be effected. Undoubtedly, the only solution for these defective juveniles was a long period of sequestration and, in many cases, permanent confinement.

Dr. Emmet Cooper Dent, Superintendent Manhattan State Hospital, West, in answer to the question about admissions to the State hospitals, said that the reports of the State Commissioners in Lunacy showed that since 1888 to 1902 there was admitted to the State hospitals: 5 to 10 years old, 7; 10 to 15 years old, 187; 15 to 20 years old, 2,618. In the Manhattan State Hospital, West, for this period: 5 to 10 years old, 0; 10 to 15 years old, 31; 15 to 20 years old, 573. He said that this would tend to show that very young persons were seldom sent to these institutions for treatment. Insanity which developed in such young persons would have a tendency to show an inherited predisposition or an unstable psychopathic state, either of which might place such a person in the class of degenerate. A degenerate properly belonged under the classification of constitutional psychopathic disorder; this classification was further subdivided by authors into (1) congenital neurasthenia; (2) compulsive insanity; (3) impulsive insanity, and (4) contrary sexual instincts. He thought this covered quite well the field of a degenerate. Under the head of compulsive insanity or obsessions this might further be divided into: (1) obsessions characterized by indecision, doubting insanity, etc.; (2) obsessions characterized by fear, agoraphobia, mysophobia, etc.; (3) obsessions characterized by propensities, dipsomania, kleptomania, pyromania, etc. He said that an obsession bore the same relation to ideas that impulses did to acts.

Respecting paranoia and degeneracy there was a difference, and they in no way resembled each other, save that both were abnormal brain development from infancy. The former was marked by a stable progressive system of delusions, whereas the latter might be called the reverse as to mental symptoms. The late lamented Dr. Godding remarked about the criminal class that there were but three things to be done with them, lock them up, kill them, or turn them loose. Before they reached the pale of criminality they were the most unsatisfactory and discouraging of all patients, due to their obstreperous and rebellious nature and not finding sufficient evidence to warrant their committal to institutions. He once was consulted in reference to a young man who ill-treated and abused his parents, spent their money lavishly, drank, gambled, etc. He had been married several times and endeavored to marry many more. He was completely void of morals or conscience, and when remonstrated with by his parents would express much surprise and assert that they were too strait-laced and he was being persecuted by them, etc. They were advised to change his environments and endeavor to employ him at some simple labor in some country place. He could not be sent to an asylum, if so he would undoubtedly have

been released on a *habeas corpus*. A house of correction was the only place left for such persons.

Dr. L. Pierce Clark said that infantile psychoses might occur in children who were abnormally precocious. Under these circumstances a child of ten or twelve years might attain the mental development of a girl or youth of sixteen or seventeen years, at which stage of mental growth various forms of degenerative insanities often occurred. He said that, however, we would expect to find, coincident with the insanity, certain definite signs of mental deficiency of the imbecile; especially defects in the faculties of perception, attention, and judgment. The signs of imbecility in such cases would take precedence over any fixed or systematized delusions, for the reason that the imbecility was congenital while the delusions were acquired.

In the early epilepsies with a strong congenital predisposition non-systematized and fleeting delusions frequently accompanied imbecile acts. Systematized delusions were rare in epileptics, either young or old. Epilepsy and paranoia were infrequently associated, possibly because the former so frequently induced dementia or marked mental enfeeblement. He had never seen paranoia, even in an imperfect form, in more than a half dozen epileptics. One associated case in a man whom he once observed was rather interesting because of his pyromania. His epilepsy began at four years of age; at six he showed an irresistible tendency to set fire to things, fortunately for the most part to things of no more account than fences. He had continued this practice for sixty years; his hands, face, and other parts of the body were almost scarred beyond recognition from frequent falls into the bonfires while in epileptic fits. Nothing but deprivation of liberty under lock and key could prevent this man from building fires. Undoubtedly if his epilepsy had not induced an early dementia he would have developed into a pyromaniac of an exceedingly dangerous sort. From his twelfth year he manifested more or less fixed delusions of a religious mystical character, which fully matured at eighteen or twenty years into a persecutory and religious paranoia. Marked dementia set in early, however, and put a stop to the further evolution of his paranoia. He was now confused and demented and quite harmless, aside from the latent possibility of his pyromania. He believed pyromania was much less frequent in the epileptic child than was often held; it seemed to require a keenness of imagination often quickly dulled by the mental degeneration of the comitial disease. He had known of but three cases in a data of some 1,500 epileptics.

The so-called psychical equivalent occasionally occurred in the epileptic child in the form of a fury, imbecilic and destructive in character, but more commonly it was an automatic state following a fit, the essential motor and sensory symptoms of which had passed unrecognized. Sexual perversions of some sort, ranging all the way from simple masturbation to that of homicidal assault for sexual gratification occurred fairly frequently in a large class of epileptic boys. But herein, again, mental enfeeblement often stepped in and prevented the further elaboration of sexual perversion.

Children who showed obsessions were usually neuropathic and manifested mental peculiarties of the imbecile. A boy he saw recently was thought to be otherwise normal, aside from his harmless obsessions of repeating certain acts, but further inquiry proved the presence of multiple stigmata of imbecility. Although he had had obsessions for four years, he had not lost control of his acts entirely. There was still some hope for improvement in such cases if the will could be strengthened.

Periodic dipsomania in the neuropathic child might show itself very early. He saw a woman of this type recently who had an uncontrollable desire for alcoholics at ten years of age. She had delirium tremens twice before she was twelve years old; from twelve to twenty-two she remained free from alcoholic excesses, but then, at the birth of her first child, she had been given whiskey, and periodically for five years following she indulged in alcohol to great excess. Alcoholic epilepsy developed six months ago.

He firmly believed that moral perversion in children as such never existed alone; careful search always showed considerable imbecility. The correction and education of the degenerative child with moral perversions was a difficult problem. It should not be undertaken while the child remained in the family. Children of this class were physically lazy, and their mental work was almost nil, and they remained for the most part idle. As they grew older they became more indifferent and shiftless and took naturally to a life of vagabondage; they lived by their wits in lying, stealing, and gambling. He agreed with Dr. Hamilton that they should be isolated early from the family and society at large; in the marked cases of moral perverts they should be permanently isolated; cared for humanely, studied scientifically, and given that degree of liberty and responsibility which they show themselves able to enjoy and not abuse. He was also in full sympathy with the President's suggestion that some curb should be placed on the circulation of bad literature among these children susceptible to moral perversion lest they be led still further into the hopeless class. It was to be deplored that vicious literature was so much without the bonds of control and ran riot in the imagination of the morally defective child.

Dr. Hamilton said his paper was intended to be only a suggestive one; he wished to see if some method could not be devised for the protection of a large number of psychopathic and unruly children who to-day were entirely misunderstood. Dr. Clark had referred to this matter, and he believed that he was strongly in accord with him. He thought all were agreed that punishment for this class of cases was to be deplored. He believed the time had come for this society to make some suggestions in the way of a report that would start the people at large to take some better protective measures. To-day children were arrested and sent to the Children's Society. They were tried, but no systematic psychiatrical examination was made. They were often convicted upon the bare facts of the case and then sent to some institution where there were no facilities for taking proper care of them. The criminal type were sent to Elmira or to the House of Refuge on Randall's Island, and he did not think that the care of these subjects in either of these places was altogether satisfactory. Of course, if any of these were epileptics they were sent to the Craig Colony where they received mental as well as other aids. He wished to lay before them the advisability of some scheme by which children who were unmanageable or ungovernable at home or elsewhere could have the advantages of some correctional school which aimed in a legal way to discipline them and in a way in accord with advanced medical science. If they were not improved in such a place, a thing he could not conceive of, they could be turned out and then managed as incorrigible. He said that they should be kept there at the pleasure of the State, but, at the same time, they should receive humane and scientific treatment.

He believed that something should be done to discourage the reading of sensational newspapers by children at large. The ordinary father pointed his finger with pride at the young boy who read the papers of the hour and absorbed their vicious contents. He said the child of to-day did not seem to be contented with the story books of more conservative and less strenuous times. Now there were, as we all know, cheap, flashy journals taken into the tenement houses; in these were found scandalous pictures, details of murders, sickly chronicles of "society," the doings of clever rascals, and the children's minds were developed along these lines. He did not think any harm could come if the society expressed itself as disapproving the present methods and attempted to try some reform

movement. He said that if it met with the approval of the society he would appoint a committee to make some practical suggestions and report in regard to some system of care, or system of training, or the establishment of special schools, or schools for manual training, or something that would make these children *think*. He believed it devolved upon them, who recognized the evil, to make some attempt to care for them and to protect society before they became criminals.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Annual Meeting, Held April 20, 1903.

ALEXANDER LAMBERT, M.D., PRESIDENT.

Aseptic Labor.—Dr. A. ERNEST GALLANT presented a paper with this title. He said that at the present time the mortality from septic infection in many of our maternity hospitals was only a small fraction of one per cent. As harmful bacteria were destroyed by the normal vaginal secretions in forty-eight hours one could no longer lay the blame for puerperal infection upon auto-infection. The dimensions of the modern obstetric bag should not be less than eight by sixteen inches, although it might be of any desired shape. The things requiring sterilization at the physician's office were the operating gown, half a dozen towels, the tape for ligating the umbilical cord, the cotton for sponges and a can of gauze. All the things likely to be needed should be spread out upon a table conveniently located for the obstetrician. In one package should be wrapped the articles which would be injured by boiling in soda and water, viz., the silkworm gut, the rubber gloves, the soft rubber catheter, and the scrub brushes. The gauze could be purchased in cans already sterilized. Similarly, cotton pads could be kept sterile in cans. When an obstetrical operation was contemplated one could not be too thorough about the sterilization of the external genitals, clipping the hair short with scissors and scrubbing the parts well with soap. The patient experienced much less discomfort if the scissors were used instead of the razor. At least five minutes should always be consumed n cleansing the hands.

New Operation for the Repair of the Perineum.—Dr. ALFRED B. TUCKER read this paper, confining it strictly to a description of the operation, which was briefly as follows: Starting at the caruncle on the left side the mucous membrane was split with blunt scissors from the skin at their junction, and this flap was dissected with the point of the scissors closed until it was possible to grasp it with a pair of artery forceps midway between the two caruncles. The scissors were then pushed up to the highest point of the rectocele, and then opened to the full extent. The dissection was then completed from without inward with the finger, holding the flap between the forefinger and the thumb. The flap was next cut out from the caruncles, completely removing it. This left a somewhat triangular denuded surface, the base of which was formed by the skin from caruncle to caruncle and the apex, the highest point of the rectocele, with a sulcus midway between the caruncle and apex. A Hagedorn needle, threaded with silkworm gut, was passed through the vaginal mucous membrane midway between the sulcus and the apex on the left side, and as soon as the needle was through the mucous membrane it was passed well beneath the mucous membrane outward and downward around the sulcus, then downward and outward through the denuded tissue and down through the sphincter muscle. The needle was then turned upward and inward, and was brought out in the median line through the denuded tissue. The suture was pulled well through and, catching the distal end of the suture with a pair of artery forceps to prevent its being drawn entirely through, the needle was passed in at the point of exit and was carried well outward and downward, and then upward, and was brought out through the mucous membrane at a point corresponding to its entrance on the other side. The second and last deep suture was carried through the mucous membrane midway between the other suture and the apex and carried downward and inward until it came out in the median line, one-eighth of an inch above the skin. The needle was then introduced at the point of exit until it came upward and outward at a point corresponding to its entrance. On drawing these sutures together the tissues were brought inward and toward each other in the median line. With a cervix needle and catgut a superficial continuous suture down to the second suture was introduced near to the apex, and tied, and then a superficial line of sutures was carried on until all of the edges of the mucous membrane were brought together and all denuded surfaces covered. After the operation the patient was allowed to urinate without catheterization, if possible, and the bowels were moved after the first twenty-four hours. The stitches were removed at the end of a week and the patient then allowed to sit up.

Dr. GEORGE TUCKER HARRISON said that the methods of performing perineorrhaphy in the past had largely ignored the true anatomical relations. This applied certainly to the operations of Hegar and Semon. Dr. Emmet's operation did have some regard to the true anatomical relations, and was the best up to that time. The operation just described seemed to him decidedly the best of all yet suggested for the repair of the perineum. The operation was attended by a very slight loss of blood, the patient suffered very little during convalescence and the results seemed to be exceedingly satisfactory.

Dr. RALPH WALDO said that he had been very much interested in this operation because it contained the elements of success in such a procedure, viz.: (1) It went well up to the posterior vaginal wall; (2) it denuded through the thickness of the vaginal mucosa, and (3) it exposed the fascia and underlying muscle. He did not like silkworm gut, however, for the suture of the perineum, because it was so liable to cut through. The best way to infect the perineum was to include the anus and the perineum in the same dressing, and hence he strongly objected to the use of the ordinary pad dressing. It was much better to leave the parts free and irrigate them when necessary with some antiseptic solution.

Dr. JOSEPH B. COOKE said that Dr. Gallant's paper was, in his opinion, one of the most practical on the subject of the conduct of labor that he had heard in the last ten years, for, in it the technique was simple and effective, and the articles to be sterilized at the physician's office had been reduced to four only—gown, towels, tape and cotton sponges. He believed that all of the so-called aseptic obstetric outfits, which necessitated preliminary sterilization of their contents, did much to prevent rather than promote the practise of true aseptis. The obstetric outfit should be, as Dr. Gallant suggested, so arranged that the greater part of the sterilization could be done at the patient's home, for it not infrequently happened that the physician was called from one case directly to another, and unless he had with him the means of effective sterilization he could not do good work. Rubber gloves he did not use except in infected cases because, confining himself to obstetrics exclusively, he seldom came into contact with pus or with any of the infectious diseases; but for the general practitioner, or even for the specialist in obstetrics and gynecology who, in the latter branch of his practice was often dealing with septic conditions, he believed the use of rubber gloves to be a *sine quâ non*. He used the permanganate method of hand disinfection in the majority of his cases, but agreed with the author of the paper that the essential feature lay in thorough and prolonged scrubbing. In the matter of internal examinations he never hesitated to make all that he considered necessary, for he felt that if the patient's vulva and the operator's hands were surgically clean no harm would result from this cause; nevertheless, he wished to emphasize most strongly the value of abdominal palpation, by means of

which, in very many cases, all but one or two vaginal examinations might be avoided.

Dr. George Tucker Harrison said he heartily agreed with the principles laid down by Dr. Gallant, but differed with him somewhat in their application. No matter how carefully the hands were cleansed it was well known that they were not sterile, and hence, he would be afraid to resort too freely to vaginal examinations. In his opinion the best method of sterilization of the hands was that recommended by Purbringer, viz., washing with 80 or 95 per cent. alcohol followed by a 1-to-1,000 solution of bichloride.

Dr. Robert Abrahams said that he did not think the outfit recommended by Dr. Gallant was altogether suitable for obstetric practice among the very poor. Those practitioners, who like himself had an extensive obstetric practice among people living in two small rooms, would probably bear him out in the statement that among them there was no mortality from puerperal sepsis and only a very trifling percentage of morbidity. Sepsis would rarely arise if the placenta were wholly expelled and all wounds of the birth-canal were promptly and skilfully sewed up. He saw no reason for condemning bichloride; in his opinion, it was exceedingly useful, although, perhaps, lysol was still better adapted for obstetric work.

Dr. James Moran said that most of his practice was among tenement-house people, and he was in the habit of giving his patients cards with printed directions and a list of things needed for confinement. This list included most of the things mentioned by Dr. Gallant. Even among the poor there was no need of having dirty sheets or dirty bedding. Physicians in general practice could not always carry around so many things, yet with a little forethought and care these could be at hand at the house.

Dr. Eden V. Delphey said that the absolute necessity for aseptic and antiseptic precautions by the obstetrician, in the conduct of labor cases, depended largely upon the habits and vital resistance of the patient. It was a noteworthy fact that the women living in the tenement districts of the east and west sides of the city had greater vitality than those living on the backbone of the island, near Fifth avenue. The lower in the social scale, the greater the resistance; the higher the social position, the less the resistance. The poor woman who was obliged to work hard every day acquired a certain immunity against physical depression and infection of all kinds, and this immunity was partly due to the fact that the healthy physiological secretions, which were always antiseptic, were more apt to be normal and free than they were in persons accustomed to ease and indolence. For these reasons some physicians, doing a large tenement-house practice in obstetrics, have very few cases of puerperal septicæmia, although their aseptic and antiseptic precautions were almost or entirely wanting.

Perineal Lacerations.—Nearly everyone who proposed or discussed operations for lacerations of the perineum seemed to think that all such lacerations were in the median line, and their operative procedures were directed accordingly. It was very seldom that such was the case; usually the lacerations were at one side or the other, and frequently they were further complicated by lateral tears into the borders of the levator ani muscle—that great diaphragm of the pelvis. These latter lacerations could be determined by hooking the bent finger toward the ischium on either side, and retracting downward. If it met resistance, the borders of the muscle were either partially or entirely intact; if it met no resistance the muscle was lacerated, and unless its edges and the accompanying fascia were brought carefully together each to each by sutures, operative repair of the perineum would be a dismal failure. It was true we might have a good apparent result; the skin and mucous membrane might be perfectly intact, but there would be no support to the pelvic contents, and the condition would be identical with that in which there was a complete laceration of the subcutaneous tissues of the perineum while the skin was intact. Nearly all of us had seen such cases. From the external surface of the perineum to the rectovesical fascia, which was superimposed upon the levator ani, there were seven different and distinct layers (five of fascia and two of muscle), and no pucker-string suture would bring them into anatomical contact, each to each; but instead would make a bunch or irregular mass of cicatricial tissue, which would give some support, but which would not be analogous to the natural perineum, nor to the repaired perineum in which the cicatricial tissue had been dissected off and the homologous parts brought carefully together with buried sutures, fascia to fascia and muscle to muscle.

Dr. Tucker, in closing the discussion on his paper, said that he had been working on his perineal operation for nine years, and had spent much time in dissections of the cadaver. He used the same operation, as far as possible, in the recent as in the secondary operation. He preferred the perineal pad to frequent douching. The urine should not cause infection if it were promptly wiped off unless cystitis was present. Last spring Dr. Studdiford, by careful dissection, found that the perineal muscles were largely made up of the levator ani muscles, the fibers of which ran in every direction and interlaced.

Dr. Gallant also made some closing remarks.

A Dog-muzzling Ordinance Desired.—At the suggestion of Dr. Alexander Lambert, the association unanimously adopted the following resolution:

Whereas, Rabies among dogs has been prevalent in this city during the past year; and

Whereas, Statistics show conclusively that the muzzling of dogs will eradicate the disease, as has been proven in Prussia, Sweden, Great Britain, Holland, and Vienna; Be it

Resolved, That the New York County Medical Association petition the Honorable Board of Aldermen of this city to pass a law requiring all dogs to be muzzled while abroad in public in this city.

Officers Elected.—The annual election resulted as follows: *President*, Dr. Alexander Lambert; *First Vice-President*, Dr. Francis J. Quinlan; *Second Vice-President*, Dr. S. Busby Allen; *Secretary*, Dr. Ogden C. Ludlow; *Corresponding Secretary*, Dr. John J. Nutt; *Treasurer*, Dr. Charles E. Denison.

A Case of Bromoform Poisoning.—Henry K. Dillard reports the case of a child of eighteen months suffering from the effects of bromoform, administered for the relief of a cough. A first dose of four drops failing to give relief a second dose of four drops was given two hours later. The child was unconscious when first seen, with pin-point pupils, which did not react to light. The face was cyanosed, lips partly open, skin cold and clammy, breathing irregular and shallow, pulse 80, weak and irregular. Strychnine and atropine were administered hypodermically, brandy and aromatic spirits of ammonia were dropped into the mouth. Lavage of the stomach was performed, and a soap-and-water enema given. A cold bath was followed by the thorough rubbing of the body and limbs. Artificial respiration was resorted to. The condition of unconsciousness continued for four hours, when the child suddenly came out of it, moved her arms and legs, cried lustily, and appeared to be fully recovered. She slept at intervals during the night, but the following morning again went into a condition of unconsciousness from which she was, however, easily aroused. She was discharged fifteen hours after admission to the hospital, apparently in good health. It is to be noted that the bromoform administered to the child was not the last in the bottle and therefore concentrated. About six fluid drachms remained in the ounce bottle after the second dose.—*Therapeutic Gazette.*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held April 27, 1903.

CHARLES N. DOWD, M.D., PRESIDENT.

The Method of Infection of Actinomycosis in Man, with a Report of Five Cases.—Dr. FRITZ MAAS presented this paper He said that, as a rule, man did not contract actinomycosis from the domestic animals, but from grain. Some of the reported cases indicated that the disease had arisen from chewing raw grain. Two cases were mentioned in which the disease was probably primary in the intestine. In one case the actinomycosis made its appearance during recovery from what the attending physician maintained was a typical attack of typhoid fever. One case has been diagnosticated as primary pulmonary actinomycosis, but this diagnosis could not be maintained in the absence of post-mortem examination. In all probability the fungus could not enter the body without a wounded surface.

The Reduction in the Infantile Mortality in New York, and the Means by Which It Has Been Accomplished.—Dr. ROWLAND G. FREEMAN presented this paper. He said that, according to the last census, the general mortality for infants under one year was 159 per thousand, and in the cities, 184, whereas in the census for 1890 this mortality in the cities was 303. Last year the infantile mortality here was only half what it was in 1892. In European countries infant mortality during the first year varied from 106 in Norway, where most of the babies were breast-fed, to 329 in Wurtemburg, where bottle feeding was very common. In the United States it was 159, and in New York city, 158. The great factors in the production of infant mortality were: (1) Heat and humidity; (2) defective feeding, and (3) bad surroundings. Heat and humidity apparently did more harm indirectly by spoiling their food than by their direct action upon infants, as was shown by the difference in its influence upon breast-fed and artificially fed infants. Statistics showed that the years marked by an unusually high infantile mortality were those in which the summers were exceptionally hot. Statistics were then presented showing that since 1892, when the Board of Health took an active part in improving the milk supply of the city, the infant mortality had markedly decreased. Not only this, but during 1889, 1900, and 1901, when there were fewer prosecutions for violations of the sanitary code regarding the impurity of milk, there was a slight increase in the death rate among infants, whereas in 1902, when the Health Department became particularly aggressive in this matter there was a decided decrease in this mortality. Other factors of considerable importance were the supplying to the poor of sterilized milk by Mr. Nathan Strauss, the work of the Floating Hospital of St. John's Guild, and the better cleaning of the city streets, as inaugurated by the late Colonel Waring. The opening of small parks, playgrounds, and recreations piers had also been of great value to the infant population. A factor that should not be forgotten was the prevention of overcrowding in the tenement-houses through the labors of the Tenement-house Commission.

Work of the Health Department in Relation to Summer Diarrhœa.—Dr. HERMANN M. BIGGS spoke on this topic. About eight years ago, he said, the Health Department established a system of issuing permits to all milk dealers after the law, as prescribed by the department, had been complied with. The use of asphalt pavements for the streets in the poorer sections of the city had done a good deal toward securing greater cleanliness and healthfulness. He thought another factor was the very material improvement in the water supply which had been affected in the past ten years. In the last two or three years only had the department undertaken a special bacteriological study of milk. This study had taught several important lessons, not the least of which was the need for better methods of transportation, especially the use of refrigerator cars for milk. The chemical composition of milk had been found in the last few years to be far less important than its bacteriology. In 1902 an attempt had been made to determine why it was that the Borough of Brooklyn had a so much higher death rate from diarrhœal diseases than the Borough of Manhattan, although prior to 1885 the reverse obtained. It was found that a much larger proportion of the infants in Brooklyn were fed on condensed milk. The previous experience of the Rockefeller Institute had shown that the mortality was higher among infants fed on condensed milk. It was found that about 60 per cent. of those who died in Brooklyn of diarrhœal diseases had been fed in this way.

Management and Prophylaxis of Gastrointestinal Disease in Infants During the Summer.—Dr. CHARLES G. KERLEY presented this part of the subject. He insisted that the most important factor in the treatment of summer diarrhœa in infants was the immediate substitution of a carbohydrate, in the nature of a cereal gruel, for the milk. A preliminary dose of castor oil was also most efficient. Dilution of the milk food was not sufficient, and it mattered not whether the milk was the best quality obtainable, or was common grocer's milk, for both afforded an excellent culture medium for germs when placed in an infected gut. If the milk were persisted in until gross lesions had developed, the case became far more serious. It was equally important not to resume the milk diet too soon. There could be no hard and fast rule, and each case must be studied by itself, yet milk should not be resumed until the temperature was normal, the stools had become thick, and were reduced to only two or three in the twenty-four hours, and even then it should be resumed cautiously and in small quantities, the effect upon the stools being carefully watched. There were a few children who could not return to milk diet until cold weather. As a milk substitute egg albumen water was not considered by him desirable. The children fed on it were slower to recover and ran a higher temperature. Animal broths he had learned to use with extreme care, and even the wine peptone preparations increased peristalsis and were often undesirable. The most common and most efficient substitute for the milk was barley or rice water, and the quantity should be about the same in ounces as the milk that had been used. The ordinary strength was half an ounce of the cereal to a pint of water. Calomel in small and frequently repeated doses should be given if there is a tendency to vomiting. The subnitrate of bismuth was of considerable value, but only when given in doses of ten to twenty grains every hour. Opium was used when there were many large, watery stools and much straining and pain. The worst possible treatment of summer diarrhœa was by giving opium and persisting in the use of milk. When opium was indicated, Dover's powder was to be preferred, given in doses of one-fourth to one-half of a grain every two hours for an infant of six to eighteen months of age. Colonic irrigations with normal salt-solution should be employed only when it was evident there was something to wash out. Usually one such irrigation a day would suffice. The salt-solution was particularly effective when there was a rapid loss of flesh and strength. In every instance such irrigations should be given by means of a long, soft tube, and the precaution should be taken to make sure that this tube was not doubled upon itself in the bowel. The greatest prophylactic agent against summer diarrhœa was a well baby, properly fed all the year round. Children who suffered much from indigestion in the cool season were apt to suffer early and severely from summer diarrhœa. The speaker insisted that 75 per cent. of the deaths among children from summer diarrhœa were wholly unnecessary. It was within the power of the municipality to do much good by placing safe milk within the reach of the poor.

Dr. W. H. LUCKETT, in discussing the first paper, exhibited a series of photographs from cases of actino-

mycosis, two of them showing actinomycosis of the bone in cattle, and two being from human subjects living in New York city and not having ever lived in rural districts. He said that it had not yet been determined whether the specific agent in actinomycosis was a fungus or a bacterium. Actinomycosis did not apparently spread through the lymphatics, but by continuity. It was by no means a rare affection, being often overlooked. He had himself met with three cases during the past year in a clinic in which other physicians had not seen one case.

Dr. Maas said that actinomycosis was so readily confounded with tuberculosis that it would often be overlooked if the diagnostician was not on the alert for it.

Dr. W. P. Northrup said that he felt like summarizing the principles of the treatment of summer diarrhœa by saying that there must be clean milk, a clean gut, and proper instruction of the mother. While in France last summer, he had been deeply impressed by the systematic effort being made by the French government to save the infants and perpetuate the race by supplying proper food and proper advice regarding infants.

Dr. W. H. Park spoke of the effort that had been made to study milk bacteriologically. This showed that while undoubtedly children fed on very bad milk were quite sick many children fed on moderately bad milk, which had been heated, did just as well as children fed on pure, unheated milk. It was found, therefore, that while the bacteriological quality of the milk was important, it sunk into insignificance as compared with proper instruction of mothers.

Tuberculosis Hospitals and Vicious Legislation.—On motion of Dr. Frank Van Fleet, the following resolution was unanimoulsy adopted:

Resolved, That the Medical Society of the County of New York believes the measure, known as the Bedell Bill, Assembly Bill No. 1, 659, is not in the best interests of the people of the State of New York, in that its enactment would practically prevent the erection of any hospital home or other institution for the treatment of pulmonary tuberculosis. The present laws are sufficient to give ample protection to outlying districts where such institutions are likely to be established and prevent their establishment for private gain. The Governor is respectfully requested to withhold his sanction of this bill. On motion of Dr. A. T. Weston, the President was requested to appoint a committee to wait on the Governor and present this action of the society.

Dr. Van Fleet also introduced the following resolution, which was adopted:

Resolved, That the Medical Society of the County of New York heartily indorses the action of the Legislature in voting an appropriation of $150,000 for the completion of the buildings of the State Hospital for Incipient Tuberculosis at Ray Brook, N. Y., and respectfully requests the Governor to indorse the appropriation in its full amount.

The Treatment of Acute Mastoiditis and Its Influence on Audition.—The conclusions of the study of J. F. McCaw on this subject are as follows: (1) Great reliance can be placed on abortive measures in the hemorrhagic variety of acute tympano-mastoiditis following influenza with a reasonably certain prognosis of normal hearing. In no other form of the disease can this be done. (2) The period of the disease at which appropriate treatment is applied influences the ultimate functional result. (3) In all cases requiring operation the earlier we attack them surgically, the greater will be the amount of hearing preserved. (4) The dry method of post-operative treatment seems to influence the function of audition, but to a less extent than early surgical interference.—*The Laryngoscope.*

Therapeutic Hints.

Bougie for Earache.—

℞	Ac. carbolici	♏ 1/2
	Fl. ext opii	♏ 2
	Cocainæ	gr. ¼
	Atropinæ sulphatis	gr. ¼

M. ft. in bougie No. 1.
Sig. Warm in water and insert into auditory canal.
—Geo. L. Richards.

Spasmodic Croup.—

℞	Hydrarg. chloridi mitis	gr. iii.
	Sacchari albi	ʒss.

M. ft. chart No. viii. Sig. One powder two hours.
To be alternated with the following:

℞	Apomorphinæ hydrochlor.	gr. ⅙
	Acidi hydrochlor. dil.	♏ij.
	Syrupi simplicis	ʒij.
	Aq. distil	ʒiiijs.

M. Sig. One teaspoonful to dessertspoonful every two hours. —L. Boyer.

Persistent Diarrhœa in Tuberculosis.—

℞	Icthoformi	ʒss.
	Tannalbin	
	Bismuth subgall	āā ʒi.
	Codeinæ	gr.iss.
	Olei menth pip.	♏iss.

M. et divide in chart No. vi. S. One powder every three to six hours, according to indications.
—*Internat. Clinics.*

Cancer of Stomach.—

To relieve pain, control vomiting, and prevent putrifaction:

℞	Bismuthi subnitratis	ʒiv.
	Ac. carbolici	♏xvi.
	Aq. chloroformi q.s. ad	ʒiii

M. S. Tablespoonful before meals.

Constipation.—

Artificial Carlsbad salt:

℞	Sodii chlorid.	ʒi.
	Sodii bicarbonat.	ʒii
	Sodii sulphat.	ʒiv.

M. S. Two tablespoonfuls in warm water before breakfast.

Epistaxis.—The latest approved method is to use a five-per-cent. solution of suprarenal extract directly upon the mucous membrane. This will at once blanch the mucous membrane and stop the hemorrhage. When the epistaxis is caused by a cardiopathic condition in old persons, the suprarenal extract should not be used.

Cardiac Debility.—

℞	Tinct. belladonnæ	gr.v.
	Tinct. nucis vom.	fl ʒxiv.
	Aquæ camphoræ	fl. ʒ

M. S. Take three times daily.

Narceine is said to be more mildly narcotic than codeine and even less likely to cause dyspepsia and constipation.

Pilocarpine is a specific for jaundice. It will relieve the pruritis concomitant to all forms, excepting when caused by hepatic carcinoma.

Nicotine is of value in tetanus. In doses of gr. 1/250 every ten minutes, full relaxant effects are sure to result.

Locomotor Ataxia and Tetanus are greatly improved by the bold administration of pilocarpine.

Erysipelas.—A piece of cotton saturated with alcohol and ignited, is held near the affected surface till a burn of the first degree appears. This is repeated three times daily until a cure is effected, which is in two or three days. The above method is said to be in use in Bulgaria.

Asthma of Hay Fever.—If blotting paper, which has been saturated with potassium nitrite is subsequently saturated with the following formula and dried, the fumes from it, when ignited, will afford great relief upon inhalation.

℞	Ext. bellad. fluidi	ʒxv.
	Tinct. benzoin	ʒxx.
	Ext. stromonii fluidi	ʒxv.

M.

Reducing Obesity.—M. C. Gerhardt finds that borax in doses of gr. 1.50 is well borne and reduces excessive corpulence.

For Pneumonia.—

℞	Ammon. carb.	gr. lxxx.
	Mucilag.	
	Aquæ	fl. ℥i.

M. S. A tablespoonful t. i. d.

When indicated, this is alternated with the following:

℞	Syr. scillæ comp.	℥iii.
	Vini ipecac.	℥iss.
	Morphinæ sulph.	gr. ss.
	Aquæ	℥iss.
	Syrupi simplicis q.s. ad	℥iv.

M. S.: One tablespoonful three times daily.

Bronchitis.—

℞	Beechwood creosote	
	Terpine	
	Iodoform	āā gr. lxxv.
	Benzoic acid	
	Larch turpentine	āā gr. xxx.
	Powdered marshmallow	
	Calcined magnesia	āā ℥iss.

M. ft. pellulæ No. c.
S. From 4 to 10 pills per diem. —Legroux.

Surgical Suggestions.

Icthyol for Hæmorrhoids.—Ten to fifteen drops of pure icthyol in capsules, taken three times daily, will cure almost all cases of hæmorrhoids, through its action upon the intestines and liver.—D. L. Bulkley.

Salt added to corrosive sublimate solution in proportion of $\frac{1}{5}$ per cent. diminishes the pain set up in mucous and raw surfaces.

Irrigating Solutions should be slightly warmer than the bodily temperature.

Or: (1) The gut is tightly wound on sections of glass tube, and the ends are secured. This prevents contraction or thickening on boiling. (2) The fat and other soluble substances are removed by soaking for twelve hours in ether. (3) The gut is transferred to a five-per-cent. solution of formaldehyde, and soaked in it for twenty-four hours. (4) The tubes are kept under constantly running water for twenty-four hours, to wash out the excess of formaldehyde. (5) Final sterilization is secured by boiling twenty minutes in water. The formaldehyde renders the gut brittle, but its tensile strength is restored by the boiling, which may be repeated one or more times without material injury to the gut. After boiling, the gut may be preserved in absolute alcohol, or it may be boiled just before use. Gut prepared in this way will resist absorption for six weeks or longer.—E. C. Dudley, *The Canada Lancet*, December, 1902.

Removing Plaster-Paris Bandages.—Acetic acid brushed in a line over the bandage will render it soft, and in a few minutes it may be easily cut with an ordinary knife.—*Applied Medicine.*

The Place of Drugs in Cardiac Dilatation.—Henry Beates considers the action of cardiac depressants and stimulants, and states that by the application of physical and physiologic laws the place of drugs is recognized as essential to the control of the diverse symptoms expressive of the predominance of this or that factor, happening to play a more or less conspicuous rôle in cardiac dilatation. If properly applied, the restoration to comfort and usefulness, as well as the prolongation of life, is sure. Too much emphasis cannot be given to the necessity of administering "active principles" and the abandonment of the ever-varying and unreliable galenic preparations. That changes in time occur in the molecular and chemical formula of these drugs must ever be borne in mind, and care taken that these derivatives be supplied only as freshly-obtained products.—*International Medical Magazine.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Fourth Annual Report of the State Board of Insanity of Massachusetts, 1902. 8vo, 59 pages. Wright & Potter Printing Co., Boston.

The Psychoses of Typhoid Fever.—Arthur W. Rogers reports two cases of persons suffering from ambulatory typhoid fever, who developed symptoms of delusion and delirium. In both the mental symptoms appeared abruptly, and the same nature of confusion as to locality and those about them was manifest. The excitement was not continuous, but appeared in a sudden and explosive manner, and was of but short duration. Both were suspicious and fearful of personal harm. Both were able to relate every circumstance correctly up to the onset of the mental complication, but between this time and the disappearance of the fever most things were a blank. A third case is reported of a man who showed symptoms of mental confusion after he was up and about, after a severe attack of typhoid fever and pneumonia. Later he became violent and had to be sent to a sanitarium, where he rapidly recovered. Regarding the prognosis of insanity complicating typhoid the author says that in cases of initial delirium coming on in the earliest stages of the fever and gradually merging into a true psychosis, only about 50 per cent. of recoveries have been reported. When a mental disturbance develops later on during the infection and during convalescence, the number of recoveries is greatly increased, being about 75 per cent. In cases of apathetic melancholia exhibiting delusions of persecution, coming on some time after convalescence has been established, the prognosis is not very favorable, numbers of the patients retaining their delusions over many months and eventually becoming demented.—*The Wisconsin Medical Journal.*

Cerebrospinal meningitis	..	3

The Nature and Treatment of Sea-sickness.—C. Binz was induced to examine a proprietary "cure" for this affection which had been used with success by a colleague who was anxious to know the nature of the remedy which had relieved his symptoms. The analysis showed that the essential constituent of the preparation was chloral hydrate, and that when taken according to directions, each dose would contain about five grains of the drug. The conclusion that the action of the "cure" depended chiefly on the vasodilating effect of the chloral on the cerebral vessels led the author to a more extended consideration of the phenomena attending sea-sickness. It is well known that the earliest symptom of the disorder is extreme pallor, which often goes on to a degree comparable to the green hue of chlorosis, owing to the thinness of the film of blood in the skin which causes it to give its complementary color. Experiments of the author and others on rabbits have shown that variations of the cutaneous blood supply of the face afford an accurate criterion of the blood supply of the brain. It appears then, that the motion of the pitching vessel in some way induces a high grade of cerebral anæmia, which is attended by its usual concomitants of intense prostration and nausea. The vomiting act is nature's effort to replenish the impoverished cerebral circulation by the congestion of the entire head, which always accompanies this function, and the stomach is not at all concerned in its causation. The proof of this lies in the temporary sense of euphoria following each vomiting paroxysm, and which makes the sufferer fondly imagine for a moment or two that now all is well and the sickness has been mastered. While it is true that the ultimate cause, that is to say, just how the motion of the ship produces the effect on the vasomotor centers, is still unexplained, this is no more difficult to understand than similar changes produced through the emotions, as in blushing, and the pallor of anger, and helpful light is thrown on the therapy. This, naturally, comprises whatever induces cerebral congestion and includes, first, position, flat or with the head lower than the body; second, diet, as good nutrition of the brain as possible through a hearty meal shortly before embarking, and, third, chemical, the use of any agents that produce dilation of the cerebral vessels.—*Centralblatt für innere Medicin.*

Spontaneous Rupture of Skin Covering in Umbilical Hernia.—W. Bishop records the case of a man, aged thirty-five years whose hernia of four years' duration came from heavy lifting. After severe exertion, he felt something give way and severe abdominal pain immediately followed. Examination showed two coils of small intestine, one within the other, lying out on the skin of the abdomen in the umbilical region. The intestine was a dark bluish-black color, without lustre. The skin was slightly discolored with venous blood, which was then oozing from the intestine. He was at once removed to hospital and operation begun. The intestines were lifted toward the ensiform, and a short median incision made in the linea alba below the umbilicus until the operator had relieved the constriction which had resulted in the gangrenous condition of the bowel. Thirty-six inches of small intestine were excised, after ligature of the mesentery and an end-to-end anastomosis made by means of a Murphy button. In concluding this operation, the operator split the fibrous ring around the umbilicus, turned the peritoneal surface inward, and, after cutting off the excess of tissue, brought the edges together with a continuous catgut suture. Mattress sutures were introduced through the skin and well back from the edge in order to bring up the rectus muscle of each side to occupy a position between the two layers of tissue formed by splitting the fibrous ring. Mattress sutures approximated the outer layer of fibrous tissue and interrupted sutures united the skin.—*Detroit Medical Journal.*

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending June 23, 1903:

ON SEPTIC THROMBOSIS OF THE ROOTS OF THE PORTAL VEIN IN APPENDICITIS AND ON PYLEPHLEBITIS, TOGETHER WITH SOME REMARKS ON "PERITONEAL SEPSIS."*

BY ARPAD G. GERSTER M.D.

NEW YORK.

NOSOLOGY.—Though septic phlebitis of the veins holding close relations to a focus of progressive bacterial infection is one of the regular stages of the process of tissue death and disintegration, the remarkable fact remains unchallenged that fortunately, in the vast majority of cases, natural provisions prevent the detachment of septic thrombi and their importation into the portal or systemic circulation. The minute detail of the manner in which the demarcation and limitation of an infectious process is accomplished *within the lumina* of those veins which contain septic thrombi is not sufficiently well known and needs further elucidation. Studies extended to this field may give us an adequate answer to the question: Why do certain thrombi become detached to be carried into the circulation as emboli, and why is this accident not more common?

Septic pylephlebitis is caused by the detachment of thrombi formed in the roots of the feeders of the portal vein which drain all the abdominal viscera, beginning from the cardia down to the anus, including also, either directly or by numerous anastomoses, the bladder and the female generative organs. Its most common cause is to be found in appendicitis.

Most authors consider the disease to be rare. Ralph Thompson[1], on the other hand, believes it to be comparatively frequent. The author's experience, based on the observation of 1,189 cases of appendicitis operated on at Mt. Sinai Hospital in the last ten years (beginning from 1892), bears out the former assumption. We have seen the disease nine times only.

Compared with the brilliant showing surgery can make in its success of coping with the various inflammatory disorders of the appendix and their grave consequences, notably with local or a more or less diffused peritonitis, this, the gravest of all possible complications of appendicitis, still remains a "partie honteuse" of modern practice.

The rarity and the utter hopelessness of the malady have, as it seems, prevented the development of a copious literature bearing on the subject which viewed from the therapeutic standpoint, seems to be one of the most inapproachable and uninviting.

Studied on the post-mortem table, the various forms of septic thrombosis of the portal vein and of its feeders can be grouped as follows:

1. *Continued Thrombosis.*—The primary thrombus is seen extending gradually and continuously or, in short intervals of space, upward toward the center, rarely involving the entire circumference of the lower course of the portal vein, but more commonly forming laterally adherent thrombi, alongside of which the blood-current may still pass with little interruption. Completely obturating thrombi are generally found near and about its entrance into the liver, either in the trunk of the portal vein, which is rare, or more commonly in one or the other, or in both of its branches. The process of infection is a slowly progressive one, *by continuity*, and results in the formation of a more or less extensive septic thrombus of unequal mass and thickness and of varying consistency.

2. *Detachment of Thrombus. Embolism and Septic Invasion of the Systemic Circulation.*—The detachment of a septic thrombus is determined by these several factors:

(*a*) Lack of firm adhesion of the thrombus to the walls of the vessel.

(*b*) Loss of consistency of the thrombus due to septic deliquescence.

(*c*) Mechanical forces acting from within or from without the body, which by lateral pressure loosen an adherent thrombus, break it up into fragments, and propel them toward the point of least resistance. Proportionately to the greater or lesser degree of solidity or deliquescence this propulsive effect of mechanical pressure will be more or less pronounced. Mechanical pressure may result from the contraction of the muscles—ileopsoas and abdominal walls—of the patient's body, or may be applied from without by a blow, by massage, or by the manipulations accompanying a surgical operation. A concussion of the body, as in a fall, may also effect the detachment of certain thrombi. Finally, the changing of the blood currents, caused by the intravenous change of the hydrostatic conditions in the affected area by incision and evacuation of an abscess, may also be sufficient to detach a broken-down thrombus. (See case of Miss Hannah A., page 1007.)

Examining the thrombi themselves on the post-mortem table, we have found great differences in their consistency and divisibility. Some had the elastic solidity pertaining to freshly coagulated blood, which is not easily broken up into fragments; others represented a shell of a more coherent, somewhat discolored material within which was contained a pasty, creamy, and viscid, or an almost fluid purulent emulsion, approaching the character of thin ichor.

It is evident that these varying physical peculiarities of the thrombi must in an important way exert their influence both upon the manner by which a detached thrombus becomes an embolus and also upon the subsequent history of the detached material.

Let us now consider in what manner the pathological processes due to septic embolism will be influenced by the consistency and corpuscular size of the detached thrombotic material.

In *continued thrombosis*, as we have seen, the extension of the thrombus is by accretion, mostly

*Read at the meeting of the American Surgical Association at Washington, May 12, 1903.

in a centripetal direction. Occasionally, however, this growth may extend centrifugally, when the thrombus of the main trunk occludes the orifice of an inosculating branch. Usually, the process is a comparatively slow one and the tendency to the grosser forms of embolic infection is not very pronounced. The thrombi being mostly lateral, the blood current is continuously washing over their surface, and in proportion as their breaking down and softening progresses, minute particles of septic material are carried off and into the branches of the portal vein, and either are arrested in, or pass through, the capillaries in which those branches terminate. Here, too, mechanical pressure may cause detachment of large emboli.

Embolism.—Larger emboli are generally arrested in the main branches of the portal vein, while, according to their size, the smaller ones will enter into the finer ramifications, the smallest detritus being stopped just this side of, or in the capillary netting of, the liver. Ichor of the very liquid kind will be best adapted to pass through this capillary barrier directly into the vena cava and systemic circulation.

Large emboli may pass directly through the substance of the liver by the way of the large venus anastomoses existing, according to Claude Bernard, between the portal vein and the vena cava.[2]

All these various occurrences may take place either singly and in succession, or may, and actually do, happen simultaneously in combination with each other.

If we consider the effects of each of these forms of transportation or invasion, we find that each calls forth phenomena characteristic of, and due to, the physical peculiarities of the transported material. It is very rare, however, that these causative conditions should not be complex; that is, that the detached material should be of uniform consistency and size; and hence the resulting phenomena must necessarily also present a mixed or combined character.

Very liquid and almost limpid ichor will, on account of its diffusibility, naturally be most apt to be displaced and be propelled on and, unimpeded even by the capillary system of the liver, readily to enter the vena cava and the systemic circulation. The effects produced will depend, first, on the quantity of the septic material thus introduced into the systemic circulation, and, secondly, on its virulence. If the quantity is large and the virulence great, the most intense forms of *intoxication*—to be well distinguished from *infection*—will result; that is, the toxins may, within a few hours, fatally poison the organism; that is, long before there is a chance for any further proliferation of the infectious bacteria contained in the injected ichor. In these cases no bacteria can be found in the blood.

It was and still is customary to attribute the end of a patient dying of heart-failure shortly after an unbloody and not exhausting abdominal operation to *surgical shock*, especially if the fatal prostration be not induced by an intense pyrexia. To the author this explanation always appeared to be inadequate, improbable, and contrary to known facts. The absence of a great traumatism and the insignificant loss of blood alone would negative the admissibility of shock. A more plausible solution of the puzzling problem, especially in cases of chronic (interval) appendicitis, will be found in the assumption of septic thrombosis and of the sudden introduction of an adequate quantity of ichor into the circulation to produce fatal toxæmia. The following history seems to offer a fair illustration of the subject:

Case I (Mt. Sinai Hospital Records, 1899, vol. iv, page 22).—Becky C., aged nineteen years, admitted June 27. Five weeks before admission she had an attack of sharp pain in the right iliac fossa with vomiting, which, however, subsided after a few days. She stated also that for six months she had had a continuous sensation of pain in the belly.

June 23. Return of severe pain in right iliac fossa with vomiting; bowels constipated. On admission the general condition was found to be good; internal organs normal, abdomen soft and relaxed. In the appendicular region no tumor was found, but there was exquisite tenderness on pressure at McBurney's point. Pulse 76 to 92; temperature 98° to 100.6° F.; urine normal.

30th. Operation under chloroform. The appendix, slightly congested, was found to be bound down by a few soft adhesions, from which it was easily liberated. The adjoining peritoneum appeared pale and glossy. Ligature and ablation of mesenteriolum and appendix, followed by thorough searing by Paquelin cautery of the stumps; complete closure of abdomen.

July 1. Vomited dark fluid five times; marked prostration; pulse weak, 130; temperature gradually rising to 101.4° F. Urine contained traces of albumin; quantity forty-three ounces. Absence of abdominal tenderness, rigidity or distension. An enema brought no stool.

2d. Vomiting more frequent, slightly tinged with blood; pulse wretched, 120 to 150 per minute; temperature 99° to 101.4° F.; urine, forty-two ounces. Local condition of abdomen unchanged, but prostration more marked.

3d. Vomiting continued; pulse 174, scarcely perceptible; patient comatose and collapsed. Temperature rose to 105.2° F. just before death. Post-mortem examination was not permitted.

The deep prostration, the feeble and rapid pulse, the cerebral intoxication, the moderate fever, all testify to an intense toxæmia, while there is no factor present to justify the assumption of shock in any form whatever. In the etiology we find the history of a prolonged, though not very intense, inflammation of the appendix, which, examined directly after the operation, exhibited a slight thickening and congestion of all its coats, notably of the mucosa, but no ulceration or any destructive process. Unfortunately no microscopic examination of the specimen was made. The presence of a deliquescent old thrombus, its displacement, and the passage of its elements into the circulation afforded the most natural explanation of the catastrophe.

If the quantity and virulence of this ichorous material be not too great, the immediate toxic effects exerted upon the circulation and the central nervous system may be overcome by the natural economy of the body. Thus a chance will arise for the proliferation of the septic microorganisms, resulting in the production of a typical case of acute and frequently fatal septicæmia. In these cases, as a rule, the blood is swarming with cocci.

The slow but more or less continuous washing off of deliquescent or liquid material by the blood current from the surfaces of lateral thrombi in continued thrombosis of the portal vein will also produce more or less intense forms of septicæmia.

The coarser material arrested in the ramifications of the portal vein will establish fixed microbic colonies in the liver, each colony surrounded by a zone of secondary thrombi and necrosis, the final result of which process is the establishment of more or less numerous liver abscesses. This form of invasion is characterized, especially in its beginning, by the symptoms of *pyæmia;* that is, by grea

oscillations of the body temperature accompanied by profuse sweats. As the fatal end of the process approaches, the pyæmic oscillations of the temperature become less typical, and the febrile phenomena assume the character of a remittent septic fever: septicopyæmia.

Symptoms and Diagnosis.—Chills accompanied by a rapid rise of the temperature, observed during the course of an appendicitis, however mild as to its local symptoms, may and usually do signify the entrance of septic material into the portal and general circulation. They must be looked upon as a sign of the gravest import. As slight a disorder as is considered to be a chronic obliterating appendicitis, may result in fatal pylephlebitis, as shown by the findings of an autopsy published by Ralph Thompson.[3]

Should the seizure pass into a continuous fever with dry tongue and skin, retching, a clouded sensorium, with a rapidly rising pulse of deteriorating volume and quality, the body temperature remaining above 103° F. with a tendency of mounting as high as 106° or higher, the diagnosis of acute septicæmia will be justified. This development may occur early or late in the course of the disease, and may be present with or without the presence and evidences of local peritonitis. When the necrosed appendix is enveloped in old and firm adhesions and is entirely walled off from the free peritoneal cavity, the surfaces of which appear to be normal, this course of events is just as often observed as where the surgeon finds a local, more or less extensive, peritonitis. Removal of the diseased appendix, evacuation and drainage of the existing abscess, or tamponade and drainage of the infected and inflamed peritoneal surface, one or all, either do not have the slightest influence upon the progress of the malady, or will cause a temporary subsidence of the symptoms only.

This intractability is due to the fact that septic phlebitis having led to thrombosis, septic material derived from a broken-down thrombus was carried into the general circulation. The morbid process thus generalized has passed beyond the line where measures undertaken against the primary focus could exert a curative influence.

Cases of this rapidly progressive and usually fatal form of acute septicæmia have been and are seen by every busy surgeon. They are readily understood when we have to deal with extensively gangrenous processes or with pronounced instances of abscess formation. The writer's first experience with this dreadful malady was made in 1895.

Case II. Miss Hannah A., aged twenty-six years, was admitted to Mt. Sinai Hospital August 17, where she had been sent by Dr. Manges from Brighton Beach. A large abscess occupied the right iliac fossa. She had been ill eleven days. The trouble had commenced with a good deal of local pain, with vomiting and fever during the first four or five days. Then the symptoms became less pronounced and a painful swelling developed in the right iliac fossa, showing deep fluctuation. There was still moderate fever (temperature 101° F.) evenings, but otherwise the patient felt pretty well, excepting as to pain caused by the abscess. Bowels had moved regularly, the belly was soft and flat, and the patient consumed and retained a considerable amount of liquid and semi-liquid nourishment. An incision of the abscess was decided upon and was done the evening of August 17. The abdominal parietes were divided layer by layer under the guidance of the eye, and the abscess was readily opened and emptied without any disturbance of existing firm adhesions which had walled it off from the free peritoneal cavity. The cavity was not flushed, but two strong drainage tubes were placed in it. Fifteen minutes after the finishing of the operation a severe and prolonged chill set in, the temperature rising to 103°F.

August 18. The fever continued, the tongue became dry, the belly remained soft and flat, was not painful to touch, and the bowels moved freely after an enema. The patient had flushed cheeks, was unusually talkative and hilarious, and assured us that she felt perfectly well, but, if let alone, would lapse into somnolence.

19th. Temperature rose to 105° F. and never descended below this figure until the end.

20th. Patient comatose and cyanosed; temperature 106.5° F.; pulse thready, 160; vomited the first time; belly soft; involuntary evacuations from the bladder and rectum.

21st. Evidences of septic nephritis and bronchitis.

22d. Died in deep coma with a temperature of 107° F. No post-mortem examination could be had.

As said before, cases of acute fatal septicæmia like this one, originating from a large appendicular abscess, are readily understood, their explanation being obvious.

But when the surgeon sees an exactly similar course taken by a case in which the local changes in and about the appendix seem trifling; when there is no gangrene, no traceable abscess; when the removal of the appendix is undertaken during the so-called "interval," to which the patient had given consent under the assurance of very small risk; when, finally, the simple and easy operation had been done under the scrupulous observance of the usual precautions by a skilful and conscientious surgeon; in short, when, in the presence of all these conditions, the patient succumbs to an acute toxæmia or septicæmia, the case is shocking and grievous indeed.

It has been customary erroneously to attribute such disasters to the importation into the peritoneal cavity of septic material by the surgeon's hands. Without denying the possibility of the fact, we shall endeavor to demonstrate that such an occurrence producing a rapidly fatal septicæmia without the previous development of peritonitis, must be exceedingly rare.

To explain these puzzling cases recourse was taken by many practitioners to the idea of a so-called peritoneal sepsis. Wagner[4], Grawitz[5], and, more recently, A. Fraenkel[6], have experimentally produced fatal septicæmia by injecting into the normal peritoneal cavity of rabbits a certain quantity of liquid septic material. It will well repay the trouble to summarize in a few sentences the findings of Fraenkel, who, repeating the experiments of Wagner and Grawitz, has rectified their conclusions in several important points.

On the injection into the peritoneal cavity of rabbits of an emulsion of septic material of known bacterial character and of an ascertained high virulence, the following facts were observed:

1. Certain animals became very sick, but in a few days recovered their health completely.

2. A certain number of the animals died in less than twenty-four hours of acute *toxæmia*. No visible changes were found in the peritoneum at the site of the injection. Smears gained from the surface of the peritoneum yielded no microbes either under the microscope or by culture, nor could, by these means, any be found in the blood.

3. If the animal did not at once succumb nor recover its normal health, the physical signs of true

infection set in. Within twenty-four to thirty-six hours after the injection reddening of the peritoneum, an exudate, and fibrinous deposits began to appear, and microbes were invariably found on and in the affected peritoneum as well as in the blood. The animals died within three to four days of acute purulent peritonitis.

4. Some of the animals survived for two or three weeks, all dying of multiple sacculated intraperitoneal abscesses.

Let us now examine whether bedside observation yields or not a parallel to the experimental facts just enumerated. The answer may be unhesitatingly affirmative as to headings Nos. 1, 3, and 4, and very reserved, if not positively negative, as to heading No. 2. Under the three headings grouped together above we readily identify conditions ordinarily met with and well known, as either the consequences of peritoneal infection due to ulcerative or traumatic perforation of a hollow viscus, or to accidental operative contamination. The complex of facts described under heading No. 2 corresponds to what has been dubbed "peritoneal sepsis."

Does a laparotomy, performed in a well-equipped hospital, by an experienced surgeon under modern canons, ever present conditions equivalent to the experimental introduction of large quantities of liquid and intensely septic matter into the peritoneal cavity?

In Fraenkel's experiments on rabbits from 1.6 to 5 c.c. of ichor were injected. To produce similar effects in the human body far larger doses would have to be incorporated, doses that would rise to the volume of one or more ounces. The accidental introduction of such quantities of septic material during an operation is simply inconceivable, and can never occur.

It may happen, however, that in the course of an operation a septic depot contained in a hollow viscus, a tube, or in the appendix, or in an encapsulated abscess, may be accidently broken into and soil the normal peritoneum without the knowledge of the surgeon. This accident is fortunately rare, but whenever it has occurred its consequence was simply an extension of the peritonitis over the soiled area. The author himself at least has never observed, nor does he know of a single case recorded in literature, in which an accidental soiling of the peritoneum by feces or pus has primarily produced anything else than peritonitis.

By these assertions an absolute negation of the possibility of a natural imitation in the human subject of events as depicted under heading No. 2 is not meant. It is only contended that their occurrence is very improbable and at best must be very rare, so rare, indeed, that it cannot be made use of to explain phenomena of sufficient frequency to be familiar to every busy surgeon.

Setting aside, therefore, both the unproven hypothesis of surgical shock and of peritoneal sepsis, the results of our observations at the bedside, the operating room, and especially at the post-mortem table irresistibly force upon our attention, as causative factors of paramount importance, *septic phlebitis and thrombosis of the roots of the portal vein and embolic processes dependent upon their disintegration.*

This theorem is in full accordance with what we know of septic pylephlebitis, and harmonizes with our knowledge of all the aspects of septic peritonitis. There is nothing fanciful or forced in it; on the contrary, it is capable of solving in a conclusive manner all doubts, dispelling the thickest of the darkness that has enveloped this important subject. The word "theorem" is used here advisedly, because, to bring the matter to actual proof, *positive demonstration* of certain facts is necessary.

Such a demonstration is attainable by the labor of the pathologist. The post-mortem table has yielded to us all the links of the chain that connects an inflammatory condition of a mesenteric vein with septic pylephlebitis and with embolic purulent hepatitis. It has put beyond any doubt the occurrence in appendicitis of fatal toxæmia, and has demonstrated that the door through which it enters is the portal vein. All that remains to be done is the visual demonstration of the existence of phlebitis and of septic thrombi in the appendicular region in such cases, in which, directly after the performance of a simple and easy aseptic "interval" operation, the patient succumbs to an irresistible septicæmia, though no demonstrable operative infection of the peritoneum be present before or after the operation.

Note.—If is significant that almost all of these mysterious cases of post-operative septicæmia occur after "interval" operations for appendicitis; that is, in those cases in which repeated attacks of a local sepsis have preceded and presumably have left behind deposits of an equivocal character.

To the author's knowledge this work is as yet undone. It would involve a much more minute and exact examination of the roots of the portal system than pathologists are wont to make. To clinch the matter it must be demonstrated in a given case: (1) That septic phlebitis and thrombosis due to appendicitis are present; (2) that no peritonitis exists; and (3) that there are no septic conditions originating in any region not drained by the porta system.

Proof of these facts will do two things: It will shed much needed light upon a dark subject, and it will remove undeserved blame from the operator, who has the misfortune to encounter a patient with a septic thrombus, which is ready to be detached and to be carried into the circulation on the slightest provocation.

We may now pass on to the consideration of the later stages of portal phlebitis. The subject is trite, all its aspects are well studied, and it will suffice to give Dr. Bryant's[7] excellent summary of the salient symptoms of the disorder: "Pyrexia, rigors, sweating, rapid pulse, abdominal pain, and tenderness in the right hypochondriac or the epigastric region, together with uniform enlargement of the liver and tenderness of that organ, especially if associated with or following any ulcerative lesion of the alimentary tract below the œsophagus, should suggest the the possibility of suppurative pylephlebitis."

The gist of the matter as to the diagnosis lies in these three propositions: (1) The presence of precedence of an infectious process involving the abdominal contents. (2) The presence of pyæmia. (3) The implication of the liver.

The diagnosis, made the first time in the living subject by Schœnlein, is not difficult when the initial affection is known, and especially when, as Fred Taylor[8] justly remarks, *the diagnostician is familiar with the disease.* Otherwise, it may be very difficult indeed. Bryant names the following diseases that have been confounded with suppurative pylephlebitis: pyæmia, septicæmia (from extra-portal causes), typhoid fever, malaria, adhesive pylephlebitis, catarrhal and other forms of jaundice, chronic catarrh of bile ducts, biliary calculus, cirrhosis of the liver; Chvostek[9] the following: catarrhal pneumonia, general septic pneumonia, empyema, subdiaphragmatic abscess, spinal caries, and rupture of a reduced hernia. Taylor adds malignant endocarditis.

To avoid error the following points may be found useful:

1. Demonstrate that the existing pyæmia or septicæmia is not caused by any lesion within the pale of the systemic circulation, and *especially not by malignant endocarditis*, a task which is very hard, when not even a murmur is demonstrable to indicate the presence of this treacherous malady.

Note.—A small but important lesion pertaining to the area of the general circulation may be easily overlooked.

2. Do not forget that the violent oscillations in the temperature (from 105° to 96° F.), which are so characteristic of the initial stages, become less and less typical as the disorder progresses. In protracted cases the fever is of a constant and remittent type, the chills disappear (Chvostek and Gerster), and the oscillations are merely accentuated by profuse sweats.

3. Again and again search for the primary septic focus in the belly.

4. Remember that the evidences of hepatic trouble are often very equivocal. Though the liver is mostly somewhat enlarged, local pressure, pain and jaundice are often absent. The enlarged spleen is not distinctive. nor do the stools offer anything characteristic.

5. A persistent local pressure along the right rectus abdominis, extending upward toward the epigastrium and accompanied by fever, observed after an appendicitis operation, and with the abdominal wound healing or healed, justifies a strong suspicion of continued pylephlebitis if there are no signs of sacculated peritonitic abscesses. (See Case IX, Mrs. L.)

Prognosis.—The prognosis is very bad, but not invariably hopeless. Chvostek[10] published the history of a case in which an hepatic abscess was incised and drained by him, resulting in the cure of the patient. Emmanuel Herczel[11] of Budapest also reports a similar case. Probably these abscesses were solitary and the virulence of the infection could not have been very great. Ralph Thompson[12] mentions recoveries reported by Loison, Sheen, and Munroe.[13] Under favorable circumstances, even a spontaneous cure may ensue. The autopsy of Case IX seems to afford sufficient grounds for this assumption.

Therapy.—It seems clear that, as regards purulent pylephlebitis caused by appendicitis, an early diagnosis of the primary trouble and prompt operation offer the only reliable safeguard.

The occurrence of a chill is of the greatest import and should be considered to constitute a more urgent indication to operate than even the signs of local peritonitis. Where much necrosis is found it would be very desirable to expose and evacuate thrombosed veins.[14] On account of their anatomical relations this is sometimes easy, oftener difficult, and mostly impossible. During the operation unnecessary pressure by retractors, sponges, or the fingers of the surgeon should be carefully avoided. Hence an incision of adequate length is necessary, and the puerile attempts at removing a diseased appendix through a mere buttonhole are to be condemned.

The evacuation of septic thrombi from the jugular vein in mastoid disease has yielded such excellent results that the application of the principle to the portal vein would be natural and logical. But the anatomical relations, while very favorable in the former instance, are just the reverse in the latter. Only a short piece of the portal vein, that situated in the hepatoduodenal ligament, is approachable. The two mesenteric veins and the splenic are practically inaccessible. Hence, though phlebotomy of the portal trunk in the hepatoduodenal ligament is not impossible, the evacuation of thrombi by flushing through a catheter seems to be too problematic, not to mention the technical difficulties the surgeon might encounter in the closure of the phlebotomy wound. The usual multiplicity of the abscesses found in the liver renders the incision and drainage of one or a few of them absolutely worthless. Chvostek's and Herczel's successes may be justly called exceptional.

In fulminant toxæmia copious infusions of saline solution would seem to deserve trial, likewise in cases of septicæmia. In one of the author's cases the employment of Marmorek's antistreptococcic serum proved of no avail; but it is proper to state that it was resorted to too late—that is, at a time when the liver was honeycombed with abscesses.

We may say, then, that the treatment will have to be simply a symptomatic one.

The histories upon which this study was based, and which were not communicated in the text, follow here:

(*a*) *Acute Toxæmia and Septicæmia.*

Case I was given on page 1006.

Case II was given on page 1007.

Case III (Mt. Sinai Hospital Reports, 1901, page 284; 1900, vol. ii, page 94).—*Acute Perforative Gangrenous Appendicitis; Large Localized Abscess; Evacuation of Abscess; Removal of Appendix; Drainage; Acute Toxic Resorption; Death Third Day Following Operation.*—Abraham S., aged fourteen years, a school-boy, was admitted in the afternoon of August 13, 1900. The present attack was the first one and was of eight days' standing. Had one chill followed by fever the day before admission. A large tumor could be felt in the right iliac fossa, very painful and tender, and bulging into the rectum; immediate cœliotomy. No free fluid was present in the peritoneal cavity. A large abscess cavity occupied the iliac fossa; when it was opened there followed a gush of fetid pus. The appendix, perforated and gangrenous at the tip, lay in this abscess cavity. It was shelled out of its peritoneal coat and ablated. The cavity was thoroughly evacuated and drained by tube and gauze. The temperature declined to 99° F. immediately after operation, but in the evening it rose to 102.6° F. The following day the temperature rose to 103.2°F., the pulse rate to 110. The discharge from the abscess cavity was profuse. The abdomen was soft and lax. The bowels moved freely and there was no vomiting.

August 15. The temperature and pulse were still high, 103.6° and 136, respectively. The urine contained a large amount of albumin and no casts. Icterus developed and the sensorium was clouded and delirious.

16th. During the night of August 15 the temperature continued rising to 104°, 105°, and finally reached 108° F. in the evening of the 16th. The abdomen continued to be soft, not tender; the bowels moved; there was no vomiting; the wound looked well; the icterus was more marked. The high temperatures and the pulse rate and the delirious condition were the only symptoms until death occurred, on August 16.

No post-mortem permitted.

(*b*) *Suppurative Pylephlebitis.*

Case IV (1894, vol. ii). *Perityphlitic Abscess; Pylephlebitis; Incision; Drainage; Death.*—Ida M. four months ago gave birth to a child; was apparently well until three weeks ago, when she began to suffer from general abdominal pain, chills, and fever Pain was not localized. Subjective history was.

very unsatisfactory; temperature 105.4° F., respiration 44; pulse 120. On admission, May 16, 1894, her general condition was poor; patient pale, anæmic and icteric; tongue dry and coated; pulse red and weak; lungs and heart negative; abdomen slightly distended; liver two fingers below free border of ribs; marked tenderness over the liver; spleen enlarged, palpable; vaginal examination negative.

May 16. Bowels moved effectually by enemata.

17th. Temperature 101.6° F.; respiration 28 to 40; pulse 108 to 130; had severe chill. Operation under chloroform. Under anæsthesia mass palpable in right inguinal region. Incision over mass. Tumor was found to be behind and outside of the peritoneum. Aspiration yielded foul pus. Tumor incised, pus evacuated from between folds of mesentery; drainage established with iodoform gauze.

18th. Temperature 99° to 105.8° F.; respiration 40 to 60; pulse 106 to 150. Patient had several severe chills; rise of temperature after each chill; is delirious at times; pulse irregular and intermittent; urine contains granular casts, bile, pus.

19th. Temperature 99° to 108° F.; respiration 48 to 64; pulse 142. Patient failed rapidly; death.

Autopsy through the Wound.—Slight jaundice; abdomen contained a moderate amount of turbid serum. Intestine: adhesive peritonitis; ileum constricted by adhesive band, causing obstruction; appendix swollen, inflamed, and perforated at the tip. In the ascending mesocolon near the appendix was an abscess the size of an egg which had been opened and drained. Spleen enlarged and septic; kidneys negative; liver somewhat enlarged. On the surface of the right lobe were two abscesses the size of a walnut. On section multiple abscesses everywhere. Septic pylephlebitis.

Case V. *Gangrenous Appendicitis; Secondary Suppurative Pylephlebitis; Abscesses of the Liver, Pancreas, and Omentum; Death.*—Keile U., aged forty-two years, Russian housewife, admitted on December 19, 1894, to Mt. Sinai Hospital, gynecological service. She was in this hospital one year ago, operated upon for salpingo-oophoritis (double). Both ovaries were removed. Was well from that time up to six months ago. For the last six months complained of pain in the lower part of abdomen. Four weeks ago had chills and fever, headache, and pain in the hypochondriac regions. These pains and the fever have continued off and on up to the present; bowels constipated; some leucorrhœa.

December 22. Transferred to medical side.

23d. Temperature fluctuated between 100.6° and 103° F.

24th. Physical examination: general condition fair; tongue coated: lungs, slight general bronchitis; heart, systolic murmur at apex; liver normal; spleen enlarged to its free border; cicatrix in median line below the umbilicus; tenderness on palpation over the cicatrix; no spots; temperature fluctuated each day between 100° and 104° F.; at times had chills. Had quinine ten grains in morning.

26th. Urine acid, clear, 1018, bile; systolic murmur over pulmonalis.

28th. Liver dulness about three fingers below free border in the mammary line. Tenderness and pleural crepitation from the angle of the scapula to base in axillary line.

31st. Had pericardiac râles over center of sternum.

January 2. Temperature subnormal and then rose to 103° F.

3d. General condition same. Temperature varied each day between 99° and 104° F.; at times chills.

4th. Transferred with the diagnosis of liver abscesses to surgical side. A careful examination of the pelvic organs elicited no positive result except the manifestations of pain on pressure, which were pretty general. No tumor could be felt in the right iliac fossa.

5th. Aspirated liver and pus withdrawn.

6th. Prepared for operation.

7th. Operation under chloroform; incision about four inches in length over region of the liver. Peritoneum found free. Liver sutured to peritoneum and abdominal walls with catgut. Wound packed with iodoform gauze and dry dressing applied.

8th. Second operation under chloroform. Liver aspirated in several places and at last found pus. Grooved director and dressing forceps introduced and opening dilated. Small quantity of pus evacuated. Drainage tube inserted, irrigated, packed with iodoform gauze, and dry dressing applied. Patient slept greater part of the night. Temperature normal.

10th. Patient's general condition poor. Septic look; refused medicine; was stimulated hypodermatically.

11th. General condition became worse and the patient died; temperature before death was 106.6 F.

Autopsy.—Liver, right lobe adherent, not enlarged; soft and septic; on section lobules not apparently congested; multiple abscesses from pea to walnut size, containing thick, green pus. Portal vein contained pus; cellular tissue around portal vein indurated and full of abscesses. Pancreas: multiple abscesses. Omentum: veins filled with pus. Intestines: appendix gangrenous and perforated; a very small abscess behind the cæcum. Spleen enlarged, soft, and septic. Kidneys enlarged, capsules not adherent; cortex pale.

Case VI. *Gangrenous Appendicitis and Pylephlebitis; Incision and Drainage of Appendicular Abscess; Transpleural Hepatotomy; Death.*—Joseph R., aged twenty-nine years, admitted to Mt. Sinai Hospital's surgical service October 27, 1899, from the medical side. History began three weeks ago with a chill, followed by fever and sweating. Such an attack was repeated daily, and then every other day; general malaise; slight conjunctival icterus. Examination: spleen enlarged to percussion, but not felt. Liver extends from sixth rib to free border; lungs and heart negative; temperature 101° to 103.4° F.; marked leucocytosis; no plasmodia.

October 21. Temperature 99° to 105.2° F.; chill.

22d. Temperature 102.6° to 105.8° F. Sausage-shaped mass in appendicular region, which was not very tender nor painful. Rectal examination negative.

24th. Daily temperatures between 101° and 103° F.; at times a chill. Mass in appendicular region persists, likewise the fever. Urine separated by Dr. Harris with segregator. Examination showed casts and albumin in both specimens. Examined by Dr. Gerster under anæsthesia. Aspirated in right lumbar region; pus withdrawn. Pus was offensive and greenish in color; temperature 98° to 105.4° F. Was transferred to surgical service.

27th. Operation; posterior incision for retroperitoneal abscess and about half an ounce of foul pus evacuated from iliac fossa.

28th. Chill; temperature 104.2° F.

29th. Foul purulent discharge from wound; violent chill; temperature 105.2° F. Daily chills and temperature rising at times to 107° F.; marked leucocytosis.

November 14. Tenderness over the liver, especially in the axillary line. Dulness over the liver in this line extending higher than normal.

Transpleural hepatotomy for liver abscess by Dr. Brewer, adjunct. Mulitiple abscesses found and drained; died a few hours later.

Autopsy of Abdominal Contents.—Liver enlarged, soft; large number of abscesses in the right lobe. In the trunk of the portal vein is a purulent thrombus; the walls of the vein are necrotic and in places eroded into an adjoining abscess cavity. Appendix retrocolic situs; tip absent. In its place is found fibrous tissue representing the abscess which had been drained by the first operation.

Case VII (Mt. Sinai Hospital Reports, 1901, p. 279). *Fulminant Gangrenous Appendicitis with Simultaneous Thrombosis of the Veins of the Mesenteriolum; Removal of a Totally Gangrenous Non-perforated Appendix Twenty-four Hours after the First Onset of the Malady. Purulent Phlebitis of Portal Vein; Multiple Abscesses and Partial Mass Necrosis of Liver; Death from Septicopyæmia Nineteen Days after Operation.*—E. O. L., aged forty-eight years, banker, a man of large stature, somewhat obese and of a florid habit; in perfect health heretofore, with the exception of a severe pneumonia passed through several years ago; had attended to his business up to noon of April 12, when he lacked appetite at luncheon and began to feel some pain in the abdomen. This was not severe enough for him to cancel a dinner party at his own house. Among the company was his family physician, who noticed that his host was rather pale and abstemious, but kept his seat at table until, late in the evening, his company dispersed.

The doctor, remaining behind, was told that the patient felt an atrocious pain in the iliac fossa. His pulse was then between 80 and 90, the temperature normal. A hypodermic injection of morphine stilled the pain. The next morning the patient reported having spent a wretched, sleepless night. Shortly after midnight a severe chill had set in, lasting an hour and fifteen minutes, ending with profuse sweat. At 8 A.M. the patient vomited. At 9 A.M. the doctor found the temperature above 104° F., the pulse 90, the pain in the iliac fossa still excessive. At 9.45 A.M. he was seen by the writer. The abdominal wall was very rigid over the site of the appendix, elsewhere soft, and pressure over McBurney's point was exquisitely painful. Rectal examination revealed nothing unusual. The temperature was falling and by noon reached 102° F. and a fraction. A slight icteric tinge was noticed in the sclerotic.

The case was declared to be a very grave one, needing speedy action, and the patient was transferred to the hospital, where the operation was performed at 1 P.M.; that is, just twenty-four hours after the first manifestation of the trouble and twelve hours after the first rigor.

The patient's internal organs, kidneys included, yielded no morbid signs.

After opening the abdominal cavity a small quantity of turbid serum escaped. Readily the dusky, almost slate-colored appendix was brought to view, its situation being rather superficial. It was nowhere confined by adhesions. Its surface appeared mottled by yellowish spots and roughened by adhering shreds of fibrin. Its distended and erect condition and elastic, hard feel demonstrated that it was filled, almost unto bursting, by liquid matter, and nice handling was required to remove it whole and unbroken. Evidently its rupture was imminent and would have been followed by the most virulent septic peritonitis. While liberating it from its mesenteriolum it was noticed that the latter was excessively brittle, permitting the ligature to cut through it immediately. And as blood flowed neither from vein nor artery, it was concluded that these vessels must be occluded—in short, that we had to deal with a mesenteric thrombosis, probably of a septic character.

The appendix was ablated close to the cæcum, was in its entirety gangrenous and filled with horribly fetid, greenish-gray ichor. While distended and *in situ* its diameter was fully three-quarters of an inch. The removed portion measured four and one-half inches.

A gauze-wick drain was placed against the appendicular stump and was brought out to the surface. Except where this wick emerged, the wound was closed in the usual manner. The patient, a cool, cheerful, and resolute man, bore the operation excellently, and in the course of the next twenty-four hours his temperature and pulse were restored to the normal standard, the former being 76 to 84, the latter 98.6° F. The peritoneal symptoms had vanished, and on the surface affairs looked promising, but apprehensions were not lulled by these appearances of peace.

April 14. Calomel and salts were given and produced a number of liquid stools. The temperature rose to 102° F., but the patient felt well and consumed and retained large quantities of liquid nourishment. During the night a slight chill occurred.

15th. A thorough examination of the wound was made, the wick-drain was removed, and was followed by a few drops of fetid serum. The belly was soft, painless, the patient expelling gases freely, and retained much liquid nourishment. Examination of the lungs showed signs of congestion corresponding to both bases; but, there being no pain and no dypnœa, it was concluded that the dull percussion sound and sharp breathing were caused by hypostatic changes—a most ominous sign. From this on the physical appearances of the lungs remained stationary to the end. The icteric hue of the sclerotics also became more noticeable. In the evening the patient vomited a large quantity of water, the melted product of much ice he had chewed and swallowed.

16th. The temperature rose to 103.4° F. with a marked chill. The wound was irrigated and dressed three times daily, discharging less and less of serum, on which floated a few drops of fat and a few shreds of necrosed tissue, evidently cast-off portions of the mesenteriolum. The belly remained soft, the bowels moving daily. The liver and spleen slightly intumescent, the former not painful to forcible pressure and manipulation.

17th. Local conditions unchanged. The urine showed no diminution of chlorides; icterus more pronounced. Urine, barring the presence of bile pigment, normal. In the afternoon a long and severe chill, the temperature rising to 105.4° F. Splenic tumor more pronounced.

From this on there were daily several more or less hard chills, followed by profuse sweating. With the chills the temperature rose to 105° and 106° F.; after profuse sweating it dropped to nearly the normal standard.

20th. During the day three hypodermic injections of fifteen grains each of the hydrochlorate of quinine and urea were given without appreciable effect, except causing slight deafness. A blood culture yielded an absolutely negative result; no plasmodia.

Though it was evident that we were dealing with a pyæmic form of virulent sepsis, our efforts were not relaxed. From this date on altogether eight injections of Marmorek's antistreptococcic serum, each dose consisting of 8 c.c., were made and very

well borne; but they did not alter the course of the malady.

21st. Albumin was found in the urine, together with renal epithelium, a few granular casts, and pus cells. The wound discharged scantily a colorless and odorless serum. The swelling of liver and spleen had markedly increased, but there was no pressure pain. Severe chill, with a temperature of 106.6° F., also the appearance of a rash, was noted.

And so it went on to the end. Chill after chill followed, the sensorium remaining perfectly unclouded to the very end. The belly remained soft, bowels active; food was well retained, except the last two days.

25th. The patient began to complain of pain in the epigastric and hepatic regions, which was augmented by pressure. He was now deeply jaundiced, and there was no doubt that we had to deal with abscesses in the liver. The urine became more and more scanty, the pulse softer.

28th. The stomach rejected all ingesta; but there was no vomiting if the patient abstained.

29th. A marked collapse following one of the usual, severe chills, but the patient rallied. Pulse remained remittent.

May 1. Out of full consciousness the patient fell back and died of heart-failure.

Autopsy, May 2, 1900.—Eighteen and one-half hours post-mortem: marked rigor; marked general icterus.

Wound.—Incision (wound) 12 cm. long in right iliac region, covered with healthy granulations leading to a sinus which leads down and in, containing some cloudy fluid; intestines adherent to the lower angle of the wound. Sinus, where the walls are covered with dark-colored fibrin, leads to appendicular stump, which is covered with fibrin. Intestinal coils adherent to each other near the stump of the appendix.

Spleen.—Enormously enlarged, flabby; congested section shows diffluent pulp; numerous small hemorrhages; 19 x 14 cm.

Kidneys.—Left, enlarged and succulent; section shows congestion and marked degeneration; capsule somewhat adherent. Right, same; more flabby. Both kidneys and capsules are bile-stained.

Liver.—Very much enlarged and congested; parenchymatous degeneration. In the portal vein there is a parietal thrombus covered by a layer of pus. Along its branches are a large number of abscesses varying in size from miliary to those of 2 cm. in diameter. In the dome of the right lobe there is an enormous number of closely-packed abscesses, between which the liver parenchyma is necrotic. Veins in the mesentery near the appendix not thrombosed.

Heart.—Right auricle markedly distended with post-mortem clots; valves bile-stained; free edge of tricuspid thickened; right ventricle moderately dilated; muscle pale. Free edge of pulmonic slightly thickened. Left auricle markedly dilated; ventricle slightly hypertrophied; no dilatation; mitral slightly thickened; endocardium between mitral and aortic valves thickened; aortic valves slightly thickened; moderate atheroma of aorta and coronaries; muscle cloudy.

Lungs.—Left: at apex, slight adhesions; emphysema of upper lobe; fibroid patch at apex; marked congestion and œdema, especially at base; bronchial glands moderately enlarged and anthracotic. Right: at apex, fairly firm adhesions; very small calcareous nodule at apex; very marked œdema and congestion, especially of the lower lobe; glands the same.

Pancreas.—Congested and degenerated. In the mesentery are two calcareous areas 1 cm. in diameter (healed tuberculosis?).

Microscopically.—Pancreas, focal necrosis; kidney, congestion, hemorrhages, marked acute degeneration, marked inflammation.

Spreads.—Spleen: very few cocci; liver: numerous streptococci.

Cultures.—Right heart, coli; left heart, coli; abscess in liver, coli, and streptococci; spleen, coli.

Diagnosis.—Appendectomy; purulent inflammation of portal vein (?); multiple abscesses of liver (streptococcus); acute hemorrhagic inflammation of spleen; chronic nephritis; acute hemorrhagic nephritis; acute degeneration of liver; hypertrophy of left ventricle; parenchymatous myocarditis; moderate atheroma of aorta; congestion and œdema of lungs; focal necrosis in pancreas.

Case VIII (Mt. Sinai Hospital Reports, 1901, p. 283). *Acute Gangrenous Non-perforative Appendicitis, with Thrombosis of the Vessels of the Mesenteriolum; Appendectomy Seventy-two Hours after Onset of the Attack; Death from Pyelophlebitis and Septicopyæmia Seventeen Days after Operation.*—Milton S., aged nineteen years, a clerk, has had several previous mild attacks of appendicitis. Three days before his admission to the hospital on October 11, 1900, he commenced to have severe pain in the right iliac fossa. Forty-eight hours later he had a chill, followed by high fever. On admission the abdomen was not distended, the right rectus muscle was rigid, and there was marked tenderness in the right iliac fossa. No tumor could be felt; his temperature was 102.8° F.; pulse 116; urine normal. Immediate operation was proceeded with. The right iliac fossa was exposed by the usual incision through the rectus sheath. The appendix was at once found, lying quite superficially on the antero-lateral aspect of the ascending colon, surrounded by adherent omentum. The appendix was rigid and erect and the blood vessels of its mesenteriolum thrombosed. The appendix was about two and one-half inches long, nonperforated, obliterated at its apex, and its mucosa necrotic. The lumen was filled with ichorous pus. The mesenteriolum was secured with a stout catgut ligature, the appendix ligated at its base, and ablated. The wound was closed by sutures, drainage being placed to the bed of the appendix.

Immediately after operation the temperature rose to 105.2° F., the pulse rate to 148. Vomiting occurred after the administration of divided doses of calomel. The temperature receded toward evening. The next day (October 12) the temperature again rose to 103.4° F., the pulse to 144; vomiting was repeated. The abdomen was soft, not tender, and the bowels moved freely. Toward evening singultus bothered the patient considerably.

October 13 and 14, the condition remained the same.

15th. The patient became delirious at times. The temperature and pulse elevations were not so high; on the other hand, icterus developed and the urine contained a few hyaline casts.

16th. There was some tenderness over the liver; the abdomen was soft; the bowels moved daily, and nourishment was taken and retained. Singultus continued to trouble the patient very much. From day to day the patient's general condition became gradually worse; the temperature daily rose to 102° and 103° F., the pulse rate proportionately; but the character of the pulse was growing gradually worse. The wound healed per primam. The abdomen remained soft; the icteric condition fluctuated in its degree of intensity; the cerebral condition was always clouded; at times delirious. The urine con-

tained albumin and hyaline casts. The tenderness over the liver was not marked.

22d. A blood culture was negative. The patient gradually grew weaker and weaker, and succumbed from exhaustion on October 28, 1900. Post-mortem examination was not permitted.

Case IX. *Gangrenous Appendicitis; Suppurative Pylephlebitis; Operation; Pyæmia; Death.*—Minnie L., aged forty-five years, housewife, had an attack of appendicitis four years ago, and again two years ago, and again four months ago. Present history began three days ago with chill and sharp pain in right iliac fossa. Pain has persisted and grown worse; has been vomiting since first day; had a second chill yesterday and another one early this morning; bowels had moved yesterday; had some fever.

On admission, April 22, 1901, the following was noted: general condition fair; tongue dry and coated; lungs, heart, spleen, and liver negative; abdomen distended and tympanitic. In the right iliac fossa marked tenderness and rigidity; rectal and vaginal examination negative. Immediate operation; Kammerer's incision; appendectomy; appendix markedly congested and swollen; gangrenous throughout; its mesenteriolum gangrenous.

April 23. Had slight chill; temperature 103° F.; urine acid, clear, 1022; no albumin; urates.

24th. Felt chilly; temperature 104° F.

25th. Packings shortened; purulent discharge from wound.

26th. Chill; increased pulse rate from 100 to 160.

27th. Pulse still rapid; free stimulation.

28th. Slight discharge from wound; general condition improved.

29th. Two chills; temperature up to 104° F.

May 5. Two to three chills daily, each lasting three to fifteen minutes; after chills temperature rose to 105° F.; pulse 90 to 150; general condition failing. The wound healed in sutured portion. Through the drainage opening there is still a slight yellowish-brown, purulent discharge.

11th. Chill; temperature rises to 107° and falls to 96.6° F. in eight hours. Complains of considerable abdominal pain, but at palpation no area of tenderness can be located. Slightly hypersensitive over liver; tongue coated with blisters; has been taking large amount of fluid and solid nourishment.

17th. A distinct systolic murmur at apex; temperature not above 103° F. for past three days; no chills from May 14 to 25; temperature during this period fluctuated between 99° and 103.4° F., and her general condition seemed to be fairly good, though the pulse continued to be rapid.

25th. Patient irrational at times; complains of some cardiac pain; heart murmur more distinct.

June 1. Temperature not above 101° F. for three days past; no chills from May 25 to time of death. Has distinct tenderness over the liver at ts lower border in the mammary line; liver enlarged and easily palpable half an inch above the umbilicus; tongue moist; takes nourishment well.

6th. Cardiac murmur louder; wound discharges less; cerebral condition improved.

26th. Complains of general abdominal pain; tenderness in left iliac fossa. Splenic dulness merges below with an area of marked flatness, which latter extended downward to the iliac fossa. Spleen enlarged and to be felt separately and distinct from this lower area of flatness. Over the left side distinct pain and tenderness. Marked fluid wave in the abdomen; general condition bad, pulse small, soft and rapid; temperature between 100° and 104° F.

July 14. No tubercle bacilli in sputum. Patient complains of severe general abdominal pain, which recurs every afternoon. Occasional attacks of cough and dyspnœa; heart action rapid and more feeble; murmur marked; temperature 103° F.

15th. Death. Urine never showed any kidney elements.

Autopsy.—Large amount of clear and opalescent fluid in the peritoneal cavity; partly sacculated in the flanks. Lungs: large amount of clear fluid with flakes of fibrin on pleuræ; both lungs congested and œdematous. Heart: slight increase of clear fluid in pericardium; slight chronic thickening of valves (tricuspid, mitral, pulmonary, and aortic); no acute lesion of valves or heart walls. Spleen large, soft, acute and septic; splenic vein negative. Kidney: slight chronic nephritis with congestion. Adrenals and pancreas negative. Liver slightly enlarged; substance soft and grayish in color. Branches of the portal vein in the liver show changes the same as described later in the portal vein proper, except that some of the smaller branches appear to be closed by fibrous tissue. Along branches of the portal veins in the liver are some whitish nodules about the size of a pinhead, which appear to be old miliary abscesses. From some of these pus exudes, but not from others. Gall-bladder small and adherent to omentum and transverse colon; contains some firm faceted stones; wall trabeculated; covered by fibrin in places; rather firmly adherent stone in the cystic duct. In the common duct is a freely movable stone; common duct is somewhat dilated. Intestines adherent to each other with sacculations of the mesentery; clear fluid; white fibrin on coils. Small intestine floats as one mass upward and forward; cæcum and ascending colon partly adherent to the abdominal wall; appendix stump hardly visible. In the pelvis is a large, irregular abscess cavity, containing green pus and bounded by the uterus below and adherent gut and mesentery on the sides and above. It lies in Douglas' cul-de-sac. Into this opens the cavity from the mesentery containing similar pus. It appears to have been due to suppuration of mesenteric veins, as near the edges pus tracts are found emptying into it, which prove to be suppurating veins. Suppurating tracts found leading up to the portal vein. Veins near the appendix stump show no macroscopic changes. Portal vein and branches: no pus in lumen nor obstructive thrombus; on the walls are firm, yellowish deposits, which appear to be the remains of parietal purulent thromboses. At its lower part the portal vein is rather narrow, and the remnants of the thrombus extend around the entire circumference of the vessel. Vena cava inferior and vena hepatica show no changes. Intestines, when opened, negative, except for slight patchy inflammation of mucosa. Mesenteric nodes moderately enlarged; in the median and left parts of the mesentery but few are seen. Supposed that some were destroyed by the suppuration. Microscopic examination of the liver demonstrates the presence of large numbers of purulent foci, many of which are quite far advanced toward organization. There are also some fibrous areas around some of the branches of the portal vein which seem to be the result of organization of the purulent foci. The wall of the portal vein shows that the thrombi were in an advanced stage of organization. Smears from the mesenteric abscess show numerous streptococci and many bacilli, some of which decolorize by Gram and others which do not. Cultures show streptococcus and b. coli.

Case X. *Acute Gangrenous Appendicitis; Thrombosis of Mesenteriolum; Septicæmia; Death.*—Eleanora Z., aged eleven and one-half years, admitted to Mt. Sinai Hospital October 13, 1901. Ordinary child-

hood diseases. Three months ago had an attack of indigestion with abdominal pain; no fever at that time, no chill. Present history of two days' standing; at onset, pain in abdomen, general at first, later localized in right iliac fossa; vomiting at onset and throughout the two days; fever of 103° F.; chill twenty-four hours after onset; no cough or expectoration. Examination: abdomen lax; in right iliac fossa a tender mass the size of an egg. Rectal examination reveals tenderness and fulness high up on right side. Immediate operation; appendix recurved, three inches long; club-shaped, dusky in color; stricture at junction of the proximal and middle third; distal third thickened and congested; its mucosa necrosed and perforated into the mesenteriolum. Appendix was removed; drainage. Diagnosis: gangrenous appendicitis and suspected portal involvement. After the operation the patient's temperature rose to 104.4° F., pulse to 120.

October 14. Child restless; no signs of peritoneal involvement; face pinched; restlessness increased, and child became apathetic; pulse more rapid; temperature varied between 99° and 105.4° F.

15th. Child in collapse and died.

No full autopsy could be secured, but the abdominal contents were removed through the incision *en masse* for examination. Appendicular stump found firm; surrounded and covered by purulent lymph; no evidences of general peritonitis; no exudite in the pelvis. Leading from the appendicular stump was a thrombosed small vein, which led up into the superior mesenteric vein; throughout its whole extent were marked changes. In places the lumen was closed by purulent material or a dark-red thrombus. At other places there was only a parietal purulent thrombus adherent to the wall of the vessel. The wall itself was not particularly affected, except for some evidences of slight inflammation involving small areas. But at irregular intervals small collections of pus were found outside and directly alongside of the vessel. The superior mesenteric vein was filled by a non-adherent, dark and soft thrombus. The portal vein was not yet involved. Mesenteric nodes were enlarged, some of them dark red. Spleen moderately enlarged and congested, its pulp soft. Liver enlarged; acute degeneration; marked inflammation with leucocytes. Kidneys: capsules not adherent; congestion; acute nephritis.

Case XI (from the service of Dr. Howard Lilienthal). *Acute Gangrenous Appendicitis and Abscess of the Mesenteriolum; Suppurative Pylephlebitis; Appendectomy; Exploratory Laparotomy for Liver Abscess; Death.*—Robert K., aged twenty-two years; present attack began December 8 with local abdominal pain, vomiting, chills, and fever. On admission, December 14, 1901, general condition was good; abdomen rigid; in right iliac fossa tender mass size of fist; rectal examination negative; temperature 103° F., pulse 110.

December 14. Ether anæsthesia; Kammerer's incision; after separation of some omental adhesions appendix appeared three or four times its normal size. Mesenteriolum very much thickened and rigid; while this latter was being tied off in sections an abscess with gangrenous walls opened near the base of the appendix. Appendix tied off and removed; drainage.

18th. A remittent constant fever continued; its cause appeared not to be influenced by the treatment.

22d. Liver dulness much enlarged; liver not tender to pressure. Pressure pain just to right of the umbilicus; right rectus still rigid; leucocytes 24,000.

26th. Liver repeatedly aspirated; from one of the punctures a drop of pus was obtained.

28th. Exploratory laparotomy to afford better facilities for aspiration; through the abdominal opening numerous aspirations were repeatedly made, but with negative results; the temperature continued to fluctuate between 101° and 104°F.; the chills were repeated.

January 6. Sudden death during the night after a severe chill.

Autopsy through Wound.—Small amount of pus about appendix stump, well walled-off; no general peritonitis; no lesion of veins immediately about the appendix stump. Many enlarged suppurating lymph nodes in mesentery; many are fused together; some connected by suppurating tracts. In two places veins found exposed by the suppuration. In these veins purulent thrombi. Portal vein shows parietal purulent thrombosis extending into intrahepatic branches. Multiple liver abscesses. In dome of right lobe large abscess with necrotic walls containing thick, tenacious pus, light brown in color. Enlarged septic spleen; kidneys congested. Spreads: in all abscesses streptococci and a bacillus positive to Gram, not growing in acrobic or anaerobic cultures. Cultures: mesenteric abscess: streptococci, b. coli, staphylococci; polymorphous, short bacillus, Gram positive. Liver abscesses: streptococcus and same bacillus as above.

Case XII (from service of Dr. Howard Lilienthal). *Suppurative Pylephlebitis Following Appendicitis; Hepatotomy and Drainage; Death.*—Foster R., aged forty years, lawyer, admitted August 20, 1902. Four weeks prior to his admission had been operated upon for the removal of the gangrenous appendix. Fever continued high after the operation; four days thereafter he had a severe chill, which was followed by a temperature of 105°. Thereafter he had repeated chills; temperature fluctuated betweer 97° and 105° F. On admission general condition was poor; temperature 104° F.; pulse 104; general icterus. Liver much enlarged, extending from fourth rib to the crest of the ilium. Free margin of liver tender; numerous friction râles over the dome of the liver. In the right iliac region was a large granulating wound and a sinus led downward to the pelvis, from which there was a profuse discharge of thin pus. Aspiration of the liver yielded thick, reddish pus.

August 21. Gas and ether anæsthesia; transpleural hepatotomy, evacuation of small abscess; collapse and death.

Autopsy.—Slight icterus, pus oozing from old appendicitis sinus. In the mesentery are large intercommunicating abscesses containing thick pus, connected by suppurating tracts which seem mainly to involve and correspond to veins; abscess also involves the lymph nodes. Veins near the site of the appendix (appendix is absent and stump covered by adhesions) do not contain pus, but are closed by firm, red thrombi: superior mesenteric vein closed by purulent thrombus; portal vein almost entirely closed by purulent thrombus extending into branches in the liver. Around branches are a large number of closed abscesses varying in size from a pinhead to 5 cm. in diameter. Some contain green pus; some brown. No pus in the subphrenic space. Liver, as a whole, congested and markedly cloudy. Lung: pneumothorax on right side; lung collapsed; spleen: acute septic. Kidneys: chronic interstitial nephritis; adrenals and pancreas negative. Bacterial examination: pus in liver; streptococci only in spreads; cultures: mesenteric abscess; spreads: streptococci and bacilli holding Gram stain; in cultures bac. coli.

(c) *Suppurative Thrombosis of Radicles of Mesenteric Vein.*

Case XIII. *Perforated Empyema of Appendix; Purulent Thrombosis of Vessels of Appendix and Neighboring Cæcum; Appendectomy; Removal of Mesenteriolum; Incision and Drainage of Thrombosed Veins; Cured.*—Isaac G., aged twenty-seven years, a presser, had never been ill until the present time. Thirty-six hours before admission he began to suffer with severe abdominal cramps; vomited repeatedly; was chilly at the onset. During his transportation to the hospital the abdominal pain subsided very materially. On admission, December 9, he looked very sick. His internal organs were normal; the abdomen was rigid and tender all over, but especially so in the right iliac fossa; free fluid in both flanks. Rectally, a tender area high up on the right side could be palpated; temperature 104°F.; pulse rate 82. Diagnosis: acute appendicitis; peritonitis. Immediate laparotomy; free exudate in the peritoneal cavity; there was a localized, thick, tenacious, but odorless encapsulated exudate in the right iliac fossa below and external to the caput coli. The appendix was found internal and below the caput coli curled up in a semicircle. It was perforated, and from the hole brownish pus exuded. The mesenteriolum was infiltrated with pus and the purulent infiltration extended up to the adjoining vessels of the cæcum. The appendix with its mesenteriolum was deligated and removed. The purulent veins of the caput were incised, curetted, and drained. During this part of the manipulation the cæcum was punctured and at once closed by Lembert sutures. Drainage of stump of mesenteriolum, appendix, and cæcal region; closure of the rest of the wound. The temperature fell after operation to 100° F. and then rose to 102.2° F., and continued for the next ten days between 100° and 101° F. There was a profuse purulent discharge from the drainage opening for a week; thereafter rapid closure of the wound. The convalescence was interrupted by a rather severe attack of tonsillitis. Discharged cured, February 2, 1902.

Case XIV. *Acute Gangrenous Appendicitis; Thrombosis of Veins of Mesenteriolum of Appendix; and Adjoining Veins of Cæcum; Appendectomy; Drainage of Thrombosed Veins; Cured.*—J. G., aged twenty-four years, a canvasser, was never sick until thirty-six hours before his admission. During the first twelve hours he felt chilly at intervals and suffered with pains in the right iliac fossa; during the last twenty-four hours he had two severe chills and vomited repeatedly, the pain in the right iliac region remaining constant. On admission, April 26, 1902, temperature was 102.4° F.; pulse 108. He was well nourished. Internal organs were normal. The lower half of the right rectus was slightly rigid. Exquisite tenderness from McBurney's point downward and inward to the pubes, but no distinct mass was to be felt. Rectally, nothing except distended intestines could be palpated. Diagnosis: acute appendicitis; probably venous thrombosis. Immediate laparotomy was proceeded with. Just before taking the anæsthetic the patient had a very severe rigor. The appendix was located anteriorly to the caput coli, lying free and surrounded by omentum. It was two and one-half inches long, dusky in color, and completely gangrenous. The vessels of the mesenteriolum contained purulent thrombi. The vessels of the caput coli could be palpated as rigid cords. This rigidity extended well up along the ascending colon. The appendix was delivered from its omental bed, its mesenteriolum was deligated at as high a point as was possible, and the appendix, after ligating its base, was removed. In the stump of the mesenteriolum could be seen the purulent thrombi in the veins. The veins in the stump and in the adjoining portion of the cæcum were slit up and drained by gauze, and the wound was closed. The patient reacted well; temperature fell during the next twenty-four hours to 99° F.; the pulse rate to 72; with chilly sensations it rose suddenly in the next four hours to 103° F., pulse rate 92; it then declined rapidly to 97.8° on the third day; thereafter it fluctuated between 99°and 100° F. There was a profuse purulent discharge from the drain opening for ten days; thereafter the wound healed rapidly.

THE LATE DR. T. GAILLARD THOMAS.*

By HENRY D. NICOLL, M.D.,
NEW YORK.

Mr. President and Fellows of the New York Academy of Medicine:

It is my sad duty to announce officially the death of Dr. T. Gaillard Thomas, a Fellow of the Academy, which took place on the 28th of February, 1903, at Thomasville, Ga.

"It has been well said that the profession of medicine is the noblest of professions, meanest of trades." Thus spoke the late Dr. T. Gaillard Thomas to the medical students of that day, in the "Introductory Address delivered at the opening of the session of the College of Physicians and Surgeons of New York, in October, 1864." His professional career, extending over a period of more than half a century, bore ample witness to the truthfulness of the first part of the quotation.

Dr. Oliver Wendell Holmes, in reply to the question as to when a boy's education should begin, answered: "At least one hundred years before he is born." According to this rule, Dr. Thomas had enjoyed very especial advantages in his education. He was descended from the Rev. Samuel Thomas, a clergyman of the Church of England, who was sent from England as a missionary to South Carolina, in the year 1700. His mother was Jane Marshall Gaillard, a connection of Chief Justice Marshall. Her ancestor, Theodore Gaillard, a Huguenot refugee, came to South Carolina after the revocation of the Edict of Nantes. With such antecedents, small wonder is it that we are able to make record of a life full of high aims and noble deeds!

Theodore Gaillard Thomas, son of the Rev. Edward Thomas, was born on the 21st day of November, 1831, on Edisto Island, South Carolina. He was educated at Charleston College, beginning his course there at the age of fourteen years. At the end of the junior year he withdrew from the

*Memorial address delivered before the New York Academy of Medicine, June 4, 1903

literary college to enter the Medical College of the State of South Carolina, from which institution he was graduated in 1852, being a little more than twenty-one years of age, and being awarded the highest honors for his graduation thesis. He came at once to New York in search of greater opportunities than his home city afforded. He arrived here in season to take part in the competitive examination for the position of interne at Bellevue Hospital. In this examination he was successful, and began his service in the hospital on the first of April, 1852, at which time an epidemic of typhus fever was raging. After completing the course in Bellevue, he went, as interne, to the Emigrants' Hospital, on Ward's Island, where he remained for six months. Being desirous to prosecute his medical studies still further, he visited Europe, in order to avail himself of the many clinical advantages to be found in the European hospitals. He passed one year in Paris in the general hospitals, and then became a resident physician in the Rotunda Hospital, Dublin, where he enjoyed peculiar opportunities for the study of obstetrics. It was in Dublin that Dr. Cornelius R. Agnew and Dr. Thomas first met, and the foundation of their life-long friendship was laid.

Returning to America in 1855, Dr. Thomas began immediately the practice of medicine in New York City. Early in his career here, in connection with Dr. W. R. Donaghe, he organized a "quiz-class" for medical students, the second of its kind in this city. The success of this class was most gratifying in two directions: the pupils were admirably trained in the various subjects, and the instructor quickly became known as a teacher of ability. The University Medical College, recognizing his talent, appointed him Adjunct Lecturer on Obstetrics. Soon afterward he was made visiting physician to Bellevue Hospital, in which institution, as interne, less than ten years before, he had had such splendid preparation for his life work. In Bellevue Hospital he continued and enlarged his system of instruction, establishing a clinical course in medical diagnosis, a new feature at that time, and one that met with high approval.

Already, as lecturer, teacher, and hospital physician, Dr. Thomas was enjoying unusual favor. Dr. John T. Metcalfe, who was described by Dr. Welch as "that admirable gentleman and doctor, a type of the best of our profession," had become so convinced of Dr. Thomas' ability and conscientious devotion to his profession, that he offered him a partnership in his private practice. This at once assured his success as a private practitioner. He was advanced to the professorship of obstetrics in the University, succeeding Dr. Bedford and holding that position until 1863.

In 1862 Dr. Thomas married Miss Mary T. Willard of Troy, daughter of John W. Willard, and granddaughter of Emma Willard, the authoress, and the founder of the Troy Female Seminary. In 1863 Dr. Thomas was made Adjunct Professor of Obstetrics in the College of Physicians and Surgeons, as assistant to Professor Gilman. Two years later he became professor of obstetrics and the diseases of women and children; and so continued until the division of this department in 1879, when he was made emeritus professor of obstetrics and diseases of women and children, and professor of gynecology. In 1881 he became professor of clinical gynecology, and in 1889 emeritus professor of obstetrics and gynecology. This steady progress upward as a teacher was not accomplished without effort. He was careful to prepare himself fully, not only as to the subject of his lecture, but he studied also to present his facts in such language and manner as to impress them upon the minds of his hearers. He devoted much time to the study of elocution, and became so proficient as a speaker that he was conceded to be one of the greatest orators in our profession.

Not satisfied with his attainments as practitioner and as teacher, upon his appointment to the Chair of Obstetrics in the College of Physicians and Surgeons, he began the preparation of his work on the "Diseases of Women." The first edition of this book appeared in 1868. The reception accorded it established its author at once in the foremost rank of the gynecologists of the world. The book has passed through six editions in English, and has been translated into French, German, Italian and Chinese, and twice into Spanish.

Dr. Thomas was appointed attending surgeon to the Woman's Hospital in 1872, and he held this position until 1887. In this hospital the greater portion of his surgical work was done, although he served as surgeon in the Strangers' and the Roosevelt hospitals. As a diagnostician he was thorough in his investigations, clear in his reasoning, and seldom incorrect in his opinions. As an operator, he worked rapidly, though most carefully; was ever ready in emergencies, and displayed always great personal interest in the care of his patients. He devised the operations of laparoelytrotomy, as a substitute for Cæsarean section, when the latter procedure was attended with a very high death rate. Dr. Thomas contributed many valuable articles to the medical journals and to the various medical societies to which he belonged.

Dr. Thomas was a member of the New York County Medical Society, the New York Pathological Society, the New York Academy of Medicine, the New York Medical and Surgical Society, a founder and several times president of the New York Obstetrical Society, a founder and one of the first presidents of the American Gynecological Society, a member of the New York State Medical Association, and of the American Medical Association. He was a corresponding member of the Obstetrical Society of Philadelphia, the Gynecological Society of Boston, the Medical Society of Lima, Peru, the Obstetrical Society of Berlin (1869), honorary member of the Washington Obstetrical and Gynecological Society, Chicago Gynecological Society, Louisville Obstetrical Society, the British Gynecological Society, and the Societè Impèriale de Mèdicine de Constantinople, and honorary fellow of the College of Physicians of Philadelphia, the Edinburgh Obstetrical Society. and of the London Obstetrical Society, and honorary member of the Obstetrical and Gynecological Society of Berlin (1894)

Dr. Thomas was a member of the Consulting Board of the old Marion Street Maternity Hospital, the Nursery and Child's Hospital, the Presbyterian Hospital, the French Hospital, the Skin and Cancer Hospital, the General Memorial Hospital, the Woman's Hospital, St. Mary's Hospital, Brooklyn; St. Joseph's Hospital, Jersey City, and the New York Infant Asylum. At the time of his death, he was president of the medical boards of the Woman's Hospital, the Nursery and Child's Hospital, and the New York Infant Asylum.

During President Cleveland's second term in office, as chairman of the "Committee on National Health Bureau of the New York Academy of Medicine," Dr. Thomas rendered the State and the nation conspicuous service. Together with other fellows of the academy, he was active in his efforts to secure a national health bureau of wide scope. He strove to obtain the appointment of an advisory council, which should represent the various parts of the country;

and he advocated, both here and at Washington, the passage of the so-called "Spooner bill." He urged in every way, not the entire abolition of quarantine, but the bringing about of a condition which should make quarantine almost unnecessary. Although Congress did not pass this measure, the efforts of the academy's committee have not been lost. A better knowledge of the needs of the country has been secured. A national bureau of health will yet be established, and the credit for inaugurating it will always belong to this committee of the New York Academy of Medicine, and to its chairman.

From the enumeration of these facts, we turn to the consideration of Dr. Thomas's character and endowments. So many touching tributes have been paid to his memory, so many prose poems have come from the hearts of his friends and colleagues, so much has been told of his noble life, that it would seem as if one man's career could hold no more of richness. And yet, from day to day, some fresh reminiscence, some new recollection of his rare gifts, develops itself in the minds of those who knew and loved him.

Many men are great in a single line in the particular profession they may have adopted. It is safe to say, that Dr. Thomas would have been equally great had he chosen any one of several other pursuits. In law, in literature, we may easily picture him as a shining light. His mind was a judicial one; his view of a situation singularly simple and direct. His comprehension of a case was characterized by unusual thoroughness and clearness of vision, and he formed his opinions with astonishing rapidity. However, although he was most decided in his views, there never lived a man more open to conviction, nay, eager for it; and he courted advice from those about him, listening to it with a mind wonderfully free from the influence of any foregone conclusion. In this respect, his character was remarkable, and indeed, really touching with its mingled elements of integrity, experience, brilliancy, child-like purity and simplicity. Few men have had so much excuse for vanity, few have been so utterly free from it. His command of literature is well known, and his own writings show refined taste, as well as power and originality. In addition to his professional essays, he wrote much in lighter vein, exhibiting great ability of expression, appreciation of incident, sense of humor, and poetic instinct—qualities which certainly make for success in authorship

It is hardly necessary to dwell upon his skill and inventive genius in the practice of his profession. These attributes were synonymous with his name, and are of world-wide repute; but the lovely character and lofty mind to which they were wedded could hardly be realized except by those who knew him. There are not many men who, attaining such prominence, have made and kept so large a number of friends, or have had so few enemies. Possessing an uncommon charm of manner and courtliness of address, he attracted and held the admiration and affection of all with whom he came in contact. A perfect host, a delightful guest, Dr. Thomas's presence at any function insured its success. His conversation sparkled with grateful allusions, appropriate anecdotes, and ready wit. His enjoyment of the society of his friends was keen and spontaneous. His domestic relations were unusually beautiful. He was a wise and devoted father, and his home was made happy by the noble influence of a companionship and inspiration which lighted his path through life.

One more characteristic must be touched upon, his deep and tireless sympathy for the poor and suffering, the esoteric essence of charity. His left hand knew not what his right hand gave. But above the material generosity of his ministrations, he conferred the inestimable gift of brotherly love, and by his kindness and compassion, raised and cheered many a suffering soul. Truly did he exemplify his own words, and in his life proved the nobility of his profession. Such a record of years well spent, such an example of what a man can be, may justly find its place in our hearts, a memory to cherish, an ideal for which to strive.

51 East Fifty-seventh Street.

A NEW BLOOD-STAIN.

By GEORGE L. LAPORTE M.D.,
NEW YORK.
INSTRUCTOR IN CLINICAL MEDICINE, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Since Ehrlich's important discovery of staining the various elements of the blood in a distinctive manner by means of combinations of various aniline dyes our knowledge of the blood has made great and rapid progress.

Ehrlich's stain was so comprehensive, differentiating nearly all of the blood elements so well, that until recently it has held supreme sway over all other stains. It is only in the last few years that it has been partially supplanted by suitable combinations of methylene-blue and eosine that will bring out as much as the triacid stain and at the same time stain the basophile protoplasm and granules and malarial parasites. Preëminent among these stains both for results and simplicity is the Jenner[1] stain. This, as is well known, consists of a powder, obtained by mutually precipitating methylene-blue and eosine in certain proportions and dissolving the resulting compound in methyl alcohol. Blood specimens are stained directly with this solution without preliminary fixation. The chief drawback to the Jenner stain is that it does not stain the chromatin of the malarial parasites distinctively. Although Jenner published his results in February, 1899, this fact seems to have been overlooked by May and Grünwald,[2] who recently published as a new bloodstain one that is exactly the same as the Jenner stain, the only difference being that Jenner has given his directions for preparing the stain a little more minutely than the authors mentioned.

In 1891 Romanowsky[3] published a new method of staining the malarial plasmodium. The stain was a mixture of methylene-blue and eosine in certain proportions and differed from other similar stains in that it demonstrated certain nuclear structures that had not been observed before. The stain was, however, exceedingly uncertain in its results, and we now know that this was due to the different qualities and age of the dyes employed, especially of the methylene-blue.

This valuable stain, therefore, owing to the unsatisfactory results it gave even in the hands of skilled observers, threatened to drop into obscurity, when Ziemann[4], in 1898, in a very painstaking and scholarly monograph, modified the stain so that with great care and extreme accuracy good results might constantly be obtained. The working of the stain was still, however, so sensitive that, for instance, the use of a different pipette in measuring the drops of one or other of the solutions would produce a failure.

Still later in 1898 and 1899 Nocht[5] discovered that instead of employing methylene-blue and eosine only, the addition of a little polychrome methylene-blue to the staining fluid would bring about constantly good and reliable results without being at all as sensitive as Ziemann's modification.

The Nocht-Romanowsky method has been found to be a reliable stain and has been used ever since. The disadvantages of this method, however, are that it requires fixing of the bloodfilm, a time for staining of from fifteen to sixty minutes and longer, and that it frequently gives rise to annoying deposits on the bloodfilm which often render it unfit for further examination.

Dissatisfied with the slowness of the Nocht-Romanowsky method and its occasional unsatisfactory results as compared with the Jenner stain, I experimented with the latter solution, trying, if possible, to obtain from it also the distinctive chromatin reaction. After various unsuccessful attempts I accidentally hit upon the addition of a little polychrome methylene-blue. A new and distinctive result was at once obtained. After extensive trials with various specimens of blood and with various modifications I finally succeeded in staining specimens of blood so as to bring out everything from eosinophile granules to the granules of mastzellen and at the same time obtain a beautiful chromatin stain.

I will now describe my method of staining: First, make a ½-per-cent. solution of Jenner's powder (Gruebler's) in methylic alcohol (Merck's, highest purity). Do not filter this solution. Secondly, make a solution of one part Unna's polychrome methylene-blue solution (Gruebler's) to 150 parts of distilled water (about 2 drops to 15 cc.). Then proceed as follows: Take the cover-glass specimen in a Cornet forceps, drop upon it 5 drops of Jenner stain. allow this to act one minute, then, without removing the Jenner stain, pour on 10 drops of the dilute polychrome methylene-blue solution. Agitate the forceps so as to produce a thorough mixing of both solutions on the cover-glass. Allow the combined stain to act five minutes longer. Then wash off with distilled water and allow some of this to rest on the cover-glass about one minute longer with occasional agitation of the forceps. At the end of this time dip the specimen rapidly into a very dilute acetic acid solution (about 1 drop of 50-per-cent. acetic acid to 10 ounces of water) until it is of a reddish or pinkish color. Rinse again with water and dry in the air. Do not employ heat or filter-paper to dry specimen.

With this stain the red blood-corpuscles will be stained a distinct pale rose. The nuclei of the white as well as of the red cells are of a bright carmine purple color (the specific chromatin reaction). The granules of the neutrophiles stand out very distinctly and are of a light violet color. The eosinophile granules are of a bright coppery red, the mastzellen granules of a very deep metachromatic blue. The protoplasm of the large and small lymphocytes is a pale light blue, dotted here and there with fine bright purplish chromatin granules. The network of the blood plates takes the carmine purple chromatin color, the bodies of the blood plates staining a light blue. The body of the malarial parasite is stained blue, its chromatin the same as the nuclei of the white cells, only of a brighter hue. Granular degeneration of the red cells appears as fine blue specks in the affected cells.

A stain constituted exactly as given above and used in the manner indicated has given in my hands perfectly uniform and eminently satisfactory results. If once made up correctly it is a very simple stain, but we must always observe a few minor details in using it. The specimens should not be fixed in any way and should not be too old. The time given for the Jenner (1 minute) and the combined stain (5 minutes) should ordinarily be strictly adhered to. It is, of course, not necessary to use always 5 drops of the Jenner solution, as with small cover-glasses 3 or 4 drops will be sufficient, but in every case double the number of drops of dilute polychrome methylene-blue solution should be used. The latter must not be added drop by drop, but in one quantity. It is also essential that the distilled water should be left on the cover-glass 1 minute longer after rinsing off the stain, as this serves to bring out more distinctly the chromatin stain. I would especially recommend to make up the Jenner stain oneself, as I have seen absolutely useless preparations sold in New York by presumably reliable dealers (one such stain being made up with ordinary common wood alcohol). Jenner recommends the thorough filtration of the stain, but I cannot see for what reason. In my own experience better results have always been obtained from an unfiltered stain, which has never deteriorated like the filtered one. The Jenner stain itself, if it is used in sufficient quantity, does not cause a precipitate; it is the water with which the stain is washed off that will do it, if not used carefully. With my stain there is never any precipitate at all

On looking up the more recent literature on this subject, I found to my surprise that Major Leishman[6] has described a method which is very similar to mine. It bears about the same relation to mine as the Ziemann-Romanowsky method bears to the Nocht-Romanowsky modification. He makes the stain by mixing a ripened alkaline methylene-blue solution with an eosine solution in the proportion of 10:1. The precipitate which results he filters off and dissolves it in methyl alcohol. The procedure of staining is very similar to mine, with the exception that he uses distilled water in place of the polychrome methylene-blue solution. The result, however, is not as good. I employed Gruebler's preparation of Leishman's stain, and obtained good results with it as far as the chromatin stain is concerned, but the red corpuscles and eosinophiles came out poorly and the neutrophile granulations were always very indistinct and frequently not stained at all. As a pure malarial stain it is certainly very good, but as a general stain it is much inferior to any good eosine and methylene-blue stain.

J. H. Wright[7] recently modified Leishman's stain somewhat in the manner of preparing the methylene-blue solution. I have not had occasion to try this stain.

About the same time that Leishman published his stain, Rueter[8] had been working on similar lines. He employed, however, absolute alcohol instead of methyl alcohol, necessitating the previous fixation of the specimens. The time of staining also was much longer, taking from ½ to 3 hours. Reuter has also been trying to isolate that part of the stain which is active in staining chromatin. He denies that it is the "red from methylene-blue" as maintained by Nocht. Giemsa,[9] after extensive investigationst, hinks that the active part is a "methylene azur," which by a new process he has been able to make in a ready and inexpensive manner. This preparation, according to Giemsa, certainly has a future in the staining of blood. It might, perhaps, be substituted with advantage for the polychrome methylene-blue in my stain; I have, however, no personal experience with this new substance.

FEEDING OF OLDER INFANTS AND CHILDREN.

By W. M. HARTSHORN, M.D.,
HOUSE PHYSICIAN, NURSERY AND CHILD'S HOSPITAL, NEW YORK.

FROM the ages of six to twelve months it is generally conceded that infants are sufficiently developed normally to digest cereal foods. It is rare that the hospital baby can stand a high milk formula, and it seems often to demand extra feeding. Cereals are recommended because they are, as a rule, easily digested and very nutritious. Individual cases must be studied by themselves, and it is only by a fair trial that any particular food can be recommended.

During the past four months all babies seven months and over in age, either artificially fed or nursed, and whose digestion seemed able to stand extra feeding, were given some stronger food. Flaked rice, cream of wheat, oatmeal gruel, farina, were all tried, but apparently the most satisfactory proved to be bread and milk. This was especially prepared. Stale bread which was twenty-four to forty-eight hours old was used. The pulp of this bread was soaked in boiling water until thoroughly softened. The water was then poured off and a cup of milk added. This was boiled for three or four minutes. After being sweetened and cooled sufficiently, it was fed to the baby.

At first a teaspoonful once a day is given, but as the infant becomes accustomed to it, this is increased, both in quantity and in frequency of feedings, until, at the end of ten days, it is receiving from one to two or three ounces daily. The time for giving this is arranged so that it comes between the regular bottle hours. Never more than half an ounce is given at one time.

If curds appear in the stools, or if, for any cause, the food disagrees with the baby, it is at once discontinued and castor oil or calomel given.

At present we have twelve babies who are receiving bread and milk prepared in this way. Most of them are babies who have suffered from intestinal trouble. As they grew older bread and milk was added to their diet with a resulting increase in weight. One advantage of this food is that it makes the transition to plain milk much easier.

Some babies seem to take the bread and milk mixture much more readily than others, and to digest it better than they do plain milk. Other babies do not care for it at all and absolutely refuse the feedings. For these babies we try to find some simple cereal which they will take.

Our older children, ranging in age from eighteen months to four years, are all fed upon plain bread and milk, with no extra preparation, at least once a day.

In the morning they generally receive farina with milk. At noon boiled rice, with meat broth poured over it, is given to them. This is made by taking Hamburg steak, one pound to a quart and one-half of water and allowing this to come to the boil. If it is allowed to boil, the meat becomes too tough. Two or three tablespoonfuls of this broth are poured over a cup of rice.

For supper they have bread and milk, the older children often receiving some plain jelly spread upon their bread.

During the fruit season they are allowed an orange or some easily digested fruit at noon. We have very few attacks of gastric or intestinal disturbances among these older ones.

Since we have been giving the extra food for the younger children and infants, there has been a marked change in the general appearance of the weight charts, so much so that our experience adds to the proof that in addition to the other cereals, bread and milk properly prepared is most valuable as a supplementary food.

Urethroscopical Diagnosis and Treatment of Chronic Urethritis.—Georges Luys of Paris, in a paper read before the International Medical Congress at Madrid, presented a new urethroscope, a modification of the urethroscope of Valentine of New York. This instrument is composed essentially of an ordinary urethroscopic tube, which is introduced into the urethra by means of a mandrin. After the tube is introduced, the mandrin is withdrawn, and in its place is introduced a small electric light mounted on a long shank, so that the illumination can be pushed to the end of the tube. A movable magnifying glass of which the optic focus corresponds exactly to the length of the urethroscopic tube, magnifies the urethral lesions and permits the examination to be accomplished in a complete manner. The small electric lamps, easily adjustable, are of different lengths and can be easily changed and adapted to long or short tubes; the former for the posterior urethra, the latter allowing a more exact examination of the anterior urethra alone. This apparatus was presented to the Société de Chirurgie in December, 1902, and has been described in the *Presse Médicale* of April 23, 1903. With it, urethral exploration can be practised in a far more precise manner than with any other method. It makes clear the recognition of polyps, vegetations, papillomata, strictures, lesions of the glands of Lithe, and the lacunæ of Morgagni. All of these lesions not diagnosed by the ordinary means of investigation are the cause of the persistence of a urethral discharge during an indefinite time. This urethroscope also gives the opportunity of urethroscopical treatment of these lesions. The treatment consists of the destruction, by means of the fine points of the galvano-cautery, of the foci which keep up chronic urethritis.

A Case of Epidermolysis Bullosa Hereditaria.—Dr. G. W. Wende reports a case of this disease. The chief points in it were the evidence of hereditary or congenital formation of vesicles and blebs at points subjected to traumatism and irritation; the marked infiltration of the skin after the lesions had subsided; the arrangement of the bullæ in concentric patches; the decided changes in the nails; the lack of hirsute growth upon the scalp; the absence of eyebrows and eyelashes; and the general tenuity of the skin. The patient was a boy of seven years, with a negative family history, if we except the fact that one brother died at the age of two years of bowel trouble, and another at about the same age, after having suffered one year from a skin disease that rendered him weaker as it progressed. Another brother is in good health. The parents are cousins, and healthy. The patient was apparently healthy at birth, and the first sign of the disease appeared concomitantly with an attack of diarrhœa, at the sixth week. The appearance at that time was of a reddening and moistening of the regions about the mouth and anus, which persisted in varying degree till an attack of cholera morbus in the

third year, when a complete remission occurred. The condition reappeared shortly, the hands and soles being covered with blebs. During the fourth, fifth, and sixth summers the disease almost completely disappeared, reappearing every winter. The patient had a good crop of hair that disappeared at the first sign of the disease. The development of the child is normal and the health is good.—*Journal of Cutaneous and Genito-urinary Diseases.*

The Separation of the Urine of the Two Kidneys in Children.—Georges Luys states that the separation of the urine of the two kidneys is as useful in the case of the child as in the adult, for surgical affections of the kidney are far from being rare at an early age. But up to the present time it has been almost impossible to accomplish such an examination, on account of the small size of the openings in the bladder of a child, and on account of the size of the instruments necessary for the separation of the urine. But the difficulties seem now overcome by the modification of the separator. In the first place the total caliber of the instrument has been lowered from No. 21 Charrière to No. 15. Another modification consists in the reduction of the curve of the vesical part of the instrument, which has been diminished so that it is more easily adaptable to the bladder of a child. Otherwise the instrument has been retained with its well-known simplicity. Excellent results have been obtained in two cases by means of this instrument: One patient was a boy of fourteen years and the other, a girl of nine years. The former patient first came for treatment on September 5, 1900, for a cystitis. The diagnosis of tuberculous cystitis seemed most probable. Although the bacteriological examination did not show any kind of microbe, a guinea-pig which was inoculated, died three weeks later with tuberculosis. On February 7, 1903, the separation of urine was made, and that from the right kidney was found to be clear, while the urine from the left kidney was purulent and bloody. From the right kidney, 9 c.c. of urine, containing 26.90 gr. of urea per liter, was obtained, while the left gave in the same time only 7.5 c.c. of urine containing only 0.64 gr. of urea per liter. The urine of the bladder contained only 10.24 gr. of urea per liter. These results determined an operation on the left kidney. The same process of separation was gone through with in the case of the second patient, and it was determined from it that the right kidney was healthy while the left was diseased. Nephrectomy of the left kidney was performed. The writer believes that these are the first two cases published of separation of the urine in children

Unilateral Ren l Hæmaturia.—A. A. Eshner gives the history of a case of this nature and follows it with an extended review of previously reported cases. He notes that various explanations have been suggested for the hæmaturia as well as for the cessation of the phenomenon after simple exposure on manipulation or incision of the kidney. No doubt the cause is not the same in every case, as the evidence goes to show. In by far the larger number of cases in which histologic examination has been undertaken lesions of an inflammatory character have been found. In some vascular changes or capsular adhesions have been noted. In a considerable number there has been mobility of displacement of the kidney sufficient to give rise to circulatory disturbances. In some, perhaps, lesions were present, though not appreciable to the naked eye. Only exceptionally could the kidney be considered healthy after histological examination. It is probable that none of the cases was an example of true hæmophilia. The suggestion of a vasomotor or angioneurotic condition does not seem an adequate explanation, and for the present it must be confessed that in a certain number of cases the cause of the hæmaturia, as well as its localization to one kidney, remains obscure. We are equally in the dark as to the mechanism through which the bleeding is controlled in the sequence of mere exposure, manipulation, or even incision of the kidney. Perhaps we have here an analogy with the recovery that sometimes follows abdominal section in cases of tuberculous peritonitis. It has also been shown that the symptoms of nephritis may be relieved by division or stripping of the capsule of the kidney or puncture of the organ, probably through circulatory modifications thus brought about. A similar explanation may be applicable to the results of appropriate operation in the presence of adhesions or displacement or mobility of the kidney.—*Pennsylvania Medical Journal.*

A Method of Intravesical Separation of the Urine of the Two Kidneys.—Georges Luys of Paris, in a paper before the International Medical Congress at Madrid, presented the advantages of his method of separating within the bladder, the urine of the two kidneys., He has made this method simple and practical by means of his separator. This instrument is composed of two metallic sounds, connected, but still independent the one of the other, and having a curve analogous to that of a Béniqué, although more accentuated; between the two sounds and at the level of their concavity, there is a rubber partition which is controlled by a (volant) shuttle-cock situated at the other end of the instrument. This apparatus has been used over two hundred times on one hundred and twenty-five different patients; fifty-six men, sixty-six women, and three children, and has always given the most satisfactory results. It can be easily disinfected; it can be boiled, and is solid and simple of construction. Every surgeon who has had a little practice in urinary affections can easily manage it, and will have no more difficulty in using it in the case of a male than in that of a female. Thus as Guyon has said, "Separation of the urine in the bladder will give new progress in diagnosis, by permitting the study of the function of the kidneys, so that it can be learned whether the lesions are unilateral or bilateral, and in case of the latter condition, to what degree the two kidneys are affected." This method of separation of the urine in the bladder, inaugurated by Lambotte of Brussels in 1890, had fallen into absolute disuse up to the time of Luys' work which dates from about three years back.

Clinical Researches on the Action of the Extract of the Medullary Substance of the Suprarenal Gland in Gastro-intestinal Atony.—Umberto Baccarani and Augusto Plessi had the best possible results from the administration of this medicament in cases of gastric atony. The sense of weight after meals, eructations, constipation, discomfort, insomnia, etc., disappeared, improvement occurring almost at once and persisting after cessation of the treatment. Cardiovascular pressure was increased, and the pulse was slightly more rapid. There were, also, evidences of beneficial action on general metabolism.—*La Riforma Medica.*

Treatment of Mastoiditis.—L. G. Woodson says that the mastoid should be opened: (1) When there is acute inflammation of the bone that resists palliative treatment. (2) When repeated swellings and abscesses occur. (3) When there is a bulging of the posterior and superior wall of the meatus, with suppuration of the middle ear. (4) When there is a fistula. (5) When there are severe pains in the same side of the head as the diseased ear, and they resist all other treatment. (6) When a foul otorrhœa cannot be cured by any other means.—*Alabama Medical Journal.*

Malaria in the Barracks in Rome from January to July, 1902.—G. B. Mariotti-Banchi concludes from his investigations that in the region in which his researches were made, the semilunar forms of the parasite which are abundant at the end of the year and the beginning of the next, completely disappear about the end of March, and are only exceptionally found until the epidemic period begins again. They are then, however, not abundant enough to explain the occurrence of the fresh epidemic. The pre-epidemic recrudescence of relapses noted in various parts of Italy, is absent.—*La Riforma Medica.*

THE GENESIS OF PULMONARY TUBERCULOSIS.

OF recent years, since the discovery of the tubercle-bacillus by Koch, comparatively little attention has been given to the histology of the tuberculous process. In the minds of some, doubt has arisen whether the bacillus is capable of exerting its deleterious effects upon healthy lung-tissue, and whether infection takes place through inspiration. With the object of elucidating a number of obscure points in connection with the pathogenesis of tuberculosis, Dr. E. Aufrecht (*Deutsches Archiv für klinische Medicin*, 75, Nos. 3–5, p. 193) undertook an extensive anatomic-histological study, and the results, while somewhat divergent from current views, are of the greatest interest and importance.

It was found that the principal and, numerically, probably the most important portal of entry for the tubercle-bacillus in the human being is constituted by the tonsils, whence the bacilli are conveyed through the cervical lymphatic glands to the mediastinal glands, in which they cause enlargement. In the living, at times in youthful persons, who come under observation for the treatment of beginning infiltration at the apices of the lungs, one or several enlarged glands can frequently be felt at the angle of the jaw on one or both sides; at autopsy enlarged, in part cheesy, mediastinal glands are found most frequently as the sole result of the activity of the tubercle-bacillus, at times in the bodies of individuals that have died from some non-tuberculous process. Caseation of cervical lymphatic glands, with the presence of tubercle-bacilli, may be found more frequently than heretofore and thus establish a direct connection with the tonsils if greater attention be given this point than it has received in the past.

The permeability of the intact walls of the blood vessels for tubercle-bacilli derived from enlarged adherent lymphatic glands having been demonstrated, it is understandable that tubercle-bacilli may be conveyed from tuberculous cervical or mediastinal glands. From the cervical veins they gain entrance into the right heart and thence into the smallest branches of the pulmonary artery; from the mediastinal glands they may penetrate directly into the pulmonary artery or into the pulmonary vein, and in the former event likewise into the lung, and in the latter event into the general circulation, and if present in large numbers give rise to general miliary tuberculosis.

That on the entrance of the bacilli into the pulmonary circulation the apices of the lungs especially should be the preferable site of lodgment is due in part to the less favorable circulatory conditions in these situations, and in part to the possibility of mechanical injury to the pulmonary tissue. As the circulation in the lungs depends upon their distention through the inspiratory action of the muscles of the thorax and the diaphragm, and in this way the flow of blood to the pulmonary vein is facilitated, this condition, as can be readily understood, is less developed at the apices. A sedentary mode of life is capable of increasing these unfavorable circulatory conditions in especial degree.

Injury to the tissues at the apices of the lungs, however, may occur as a result of violent respiratory action, because under such circumstances the sternomastoid and the scaleni muscles contract and their extreme degree of functional activity is opposed to that of the diaphragm. Also severe paroxysms of cough must cause stagnation of air in the apices of the lungs, because these are covered only by soft tissues, which do not take part in expulsion of the air. It is not impossible that all of these conditions alone, that is prior to the invasion of the tubercle-bacillus, may result in histologic injury to the tissues at the apices of the lungs. When, however, the tubercle-bacilli have become adherent to the walls of the smaller vessels in the apices of the lungs, they undergo multiplication and give rise to an increase in the cellular elements of the vessel-wall, and this becomes so marked as to create an appearance in section of circumscribed accumulation of cells that have heretofore been looked upon as newly-formed granulations, as gray tubercles.

While in the liver almost always this change alone, namely, the gray tubercle, that is, a considerable thickening of the vessel-wall takes place, the thickening of the vessel-wall in the lungs, as well as in the spleen and the kidneys, gives rise to nutritive disturbances in portions of tissue supplied by these vessels, and resulting in necrosis, without, though still more frequently with, thrombotic occlusion of the lumen of the vessels, because these organs have end arteries. The bacilli gain entrance into these necrotic areas from the vessel-wall, and thus the caseous tubercle is produced. It is the product of the combined activity of the necrosis and the tubercle-bacilli.

The extent of the anatomic alteration in the lungs brought about by the tubercle-bacilli entering through the vessels is dependent upon the number of bacilli, but probably also upon the amount of minute particles of necrotic organic substance such as occurs in caseous masses. In the presence of small numbers of tubercle-bacilli that have penetrated as such through the intact walls of the vessels there occurs the formation of isolated foci only in the apices of the lungs, while in the presence of large numbers of bacilli enormously large numbers of caseous tubercles develop in the lungs and eventually in all portions of the lungs. In the former event cicatrization may take place, or after extrusion of the necrotic caseous area a small cavity may form in the apex of the lung; in

the latter event death may result, usually after a rapid course, although recovery appears not impossible.

When it is borne in mind that extensive tuberculosis of the peritoneum may undergo perfect recovery, leaving fibrous tubercles as the remains of caseous tubercles whose necrotic products have been absorbed, the possibility of a similar process in the lungs must be admitted. If, however, the lung possesses the unfortunate advantage, in consequence of the presence of cheesy tubercles arising from disease of the walls of the vessels, of being exposed to most extensive tissue-destruction or cavity-formation, this depends not upon the caseous tubercles, directly but upon the pneumonic process due to their presence, and which gives rise to exudates into the alveoli as well as into the interstitial tissue, and thereby lays the foundation for the entrance of tubercle-bacilli from the caseous tubercles. The formation of cavities of considerable size results only from the disintegration of pneumonic-infiltrated tissue.

In the presence of isolated caseous tubercles in the apices of the lungs the pneumonic process remains confined to these localities. Under suitable treatment it may undergo resolution or result in chronic pneumonia or cavity-formation. If the entire lobe of a lung or an entire lung is filled with caseous tubercles, the correspondingly extensive pneumonic process gives rise to desquamative pneumonia or caseous lobar pneumonia.

The problem of discovering a remedy for the destruction of the tubercle-bacillus and thus for the prevention of the development of the caseous tubercle is to be solved by specific therapy. Upon hygienic-dietetic therapy (altitude, sanatoria) is placed the obligation, from the results of the foregoing investigation, to avoid the pneumonic processes, which first constitute the type of pulmonary phthisis and comprise the great danger that the tuberculous patient may become phthisical; and if already present to limit the disintegration of the parts to the seat of the pneumonic process. Empiricism, which has long preceded scientific explanation and reasoning, demonstrates adequately that such endeavors will be attended with success.

THE ETIOLOGY OF SLEEPING SICKNESS.

An editorial note which appeared in the Medical Record, April 25, commented on the news reported by Dr. Aldo Castellani, one of the members of the commission sent out by the British Royal Society to Uganda, to investigate into an outbreak of sleeping sickness there, that he had found an organism which he had good reason to suppose was the cause of sleeping sickness. It is rather more than one hundred years ago since the first account of this disease was published by Winterbottom. In the intervening period Corre, Hirsch, and Stephen Mackenzie have investigated into and written on the subject, although perhaps the most complete history of the malady, considering the then state of knowledge, was that by Clark. Manson was one of the first to suggest that the disease might be of parasitic origin. Writing in "Allbutt's System of Medicine" in 1897, he threw out the hint that filaria perstans might be responsible for sleeping sickness. Several germs have been at one time and another described as the cause of the peculiar disease which affects the natives of certain districts in Africa known as sleeping sickness or negro lethargy. In 1897 two Portuguese medical men declared that they had succeeded in isolating a bacillus from the blood of a patient suffering from sleeping sickness, which when injected into animals would reproduce the disease, but these experiments were not confirmed by other investigators. Marchoux, from the result of his observations, came to the opinion that sleeping sickness was due to Fränkel's diplococcus, and, lastly, there have been the bacteriological researches of the Portuguese Commission, of Dr. Broden, director of the bacteriological laboratory at Leopoldville, and of Dr. Castellani.

Dr. Castellani, in the preliminary notes he published in the *Lancet* and *British Medical Journal*, both of March 14, and which were referred to in the Medical Record of April 25, stated his decided opinion that he had isolated a new germ in sleeping sickness, a brief description of which was given in the aforesaid journals. He further differentiated it from the diplostreptococcus discovered by the Portuguese Commission, in that the culture of their germ generally failed every time on the usual media, like agar, gelatin-agar, etc., and with gelatin they never succeeded in obtaining cultures at all. So far it seemed as if Dr. Castellani had made good his claim as the dicoverer of the germ of sleeping sickness.

An article, however, appeared in the *Lancet*, May 23, which puts an entirely different complexion on the matter. Drs. Annibal Bettencourt, Ayres Kopke, José Goures de Rezende, Jr., and Annibal Correia Mendes, the members of the Portuguese Commission place on paper their side of the question. They state that on August 10, 1900, in Loanda, they first proved the existence of a diplostreptococcus in the cerebrospinal fluid and in the subarachnoid exudate in cases of sleeping sickness, but that the principal characters of the germ could only be demonstrated in an imperfect and summary way, owing to the absolute impossibility of making a complete study of it up to that date. These results were published in September, 1901. In August, 1902, after many further researches, the existence of the parasite was confirmed, and it was particularly pointed out that the microorganism ought to be included in the streptococcus group, and it was proposed to give to it the name "hypnococcus." It was described in the second report as growing on gelatin and other media at a temperature lower than 24° C., and as also growing well in His's fluid, the reaction not being modified, nor the fluid coagulating after a month's stay in the incubating oven. Castellani's contention, therefore, that the germ isolated by the Portuguese, and that discovered by him, could not be the same, because the culture of their germ generally failed nearly every time on the usual media like agar, gelatin-agar, etc., must lose its force.

The Portuguese Commission say that Castellani's statement was founded upon a misconception, as when he made it he had only seen their first report. The commission then say "months before the publication of Castellani's work we published a

description of our cultures on agar, bouillon, and potato, in which we obtained identically the same result as he obtained. We also pointed out the absence of the coagulation of milk, and the absence of gas production in the media containing glucose, in respect of both of which characteristics Castellani agrees perfectly with us. . . . How can it be suggested that the bacteria so often isolated by us in pure cultures may not be the same as the one seen in the sections and exudates, the identical morphology being given? And how can the germ isolated by Castellani from the same regions of the body as we obtained it during life and post-mortem examination, not be the same we saw in our microscopical sections?" With regard to finding the germ in the blood of those suffering from sleeping sickness, the Portuguese isolated it twice and Castellani once. The difference of opinion between the Portuguese Commission and Dr. Castellani as to priority of discovery of the germ of sleeping sickness, appears to lie in the fact that Dr. Castellani only saw the commission's first report, which was avowedly incomplete and to some extent perhaps inaccurate or rather misleading. In the second report the conclusions arrived at by the commission —judging from the article in the *Lancet*—seem to agree in nearly every particular with those of Dr. Castellani. It is a pity that the latter had not seen the second report before publishing the result of his investigations. There is one feature in the situation that must strike a note of satisfaction in the breasts of scientific men, that both the Portuguese and Castellani are convinced, that the germ discovered independently is in verity the true cause of sleeping sickness.

THE DISTRIBUTION OF THE KLEBS-LÖFFLER AND HOFFMANN BACILLI.

It has long been known that the results of bacteriology and of clinical medicine were not in accord so far as the question of diphtheria goes, many persons whose cultures have been pronounced "positive" having no evidence of diphtheria in the clinical sense. And of course, isolation on *a priori* grounds must often, to them, have seemed a hardship. It is therefore of great importance to determine whether such persons are dangerous to others, and to what extent. This is what Dr. G. S. Graham Smith has attempted. In the *Journal of Hygiene* for April, 1903, he discusses the question of the distribution of the Klebs-Löffler and Hoffman bacilli in the throats of those who have been in contact with diphtheritics ("contacts"), and in those of normal persons. His conclusions are, in brief, that the Klebs-Löffler bacillus has been found in a considerable proportion of persons who have been in contact with cases of diphtheria, or with infected persons. Such persons have been shown to be a grave danger to public health, especially when they are frequenting schools or institutions, and they constitute the usual channel by which the disease is spread. Very satisfactory results have followed the isolation of convalescents from the disease and of infected "contacts," until two consecutive negative cultures have been obtained. Carefully conducted investigations among healthy persons who have not been in contact with cases of diphtheria or with infected "contacts," have shown that virulent diphtheria bacilli are very rarely found in the mouths of the normal population, they being actually found only three times in 1,511 examinations. This fact renders the discovery and isolation of infected persons a practical possibility, and offers a fair prospect of discovering and isolating the majority of them in any outbreak. Diphtheria bacilli are usually distinguishable on morphological and cultural grounds, but whenever possible, it is desirable that their virulence be tested. The bacillus of Hoffman is inocuous to man. It is a very common organism in the mouths of the poorer classes. The distribution of this bacillus points to the conclusion that it is carried from mouth to mouth in the same way as the diphtheria bacillus, and therefore its wide prevalence in schools attended by poorer children, is significant as showing how wide-spread and uncontrollable an outbreak of diphtheria may become, unless measures are taken early to deal with infected "contacts."

Annual Report of the Matteawan State Hospital.

The medical superintendent of the Matteawan State Hospital has just issued the forty-third annual report of that institution for the year ending September 30, 1902. Owing to a part of the new hospital, now in course of construction at Dannemora, being ready for the admittance of patients, all the male convicts who remained at Matteawan under sentence for felony have been removed thither. This action relieved Matteawan of all male felons under sentence, excepting those who had but a few months to serve. During the past three years the total number of patients transferred to Dannemora, plus those sent to the other State hospitals by order of the State Commission in Lunacy, was 228. Consequently the overcrowding at Matteawan has been so greatly lessened that the necessity for relief by transfer to State hospitals has ceased to exist. No male patients are now received at Matteawan from the State prisons, nor from the New York State Reformatory at Elmira. The only class of felons now admitted consists of women.

Regarding the manner of disch rge of the convict or criminal who is, or who has been insane, the report draws attention to the fact that more interest pertains to this question than attaches to the release of the ordinary insane. The reason is that a majority of the former class awakens a sense of uneasiness because of their dangerous tendencies toward the commission of unlawful acts. Any person who is insane, even a quiet, chronic patient not a criminal, is a source of more or less anxiety on the part of friends, and the community when he is at large. "What disposition should be made of the criminal insane, therefore," says the report, "when the occasion arrives for him to leave the hospital, is a matter of some concern. Out of the total number of ninety-seven discharges, less than 26 per cent. were released by the hospital authorities. The State Commission in Lunacy for special reasons transferred four cases to other hospitals for the insane. The new hospital at Dannemora received over one-third of all who were discharged from Matteawan, the custody of all these cases being simply transferred from one hospital to the other. "The ratio of recoveries, as at other institutions of a like nature, has always been extremely small at Matteawan. The ratio of recovery for the year just closed, based upon the average daily population, was 2.50 per cent., and 2.16 per cent. upon the

whole number treated. The death rate at Matteawan has, too, always been exceedingly small and much below the usual percentage reported at other hospitals. The ratio of deaths, based upon the average daily population, was 2.83 per cent., and 2.45 upon the whole number treated. A little more than one-half of all the deaths occurred from tuberculosis. The weekly cost of maintenance at Matteawan, based upon the daily average population, was $3.42. The total annual cost was $178,274. The Matteawan State Hospital, judging from its latest report, would appear to be in a satisfactory condition.

Diphtheria in Relation to Domestic Animals.

In some cases animals have been shown to spread disease among men, and within recent years various domestic animals and birds have been regarded with grave suspicion as possible conveyors of infectious maladies to the human race. Members of the canine tribe are asserted to be a not infrequent source of hydatid disease. With less ground for assertion, cats have been stigmatized as the cause, occasionally, of disseminating scarlet fever, while parrots would seem to have been rightly accused as the means whereby a highly infectious disease, to which these birds are subject, has been spread among the human race.

In *Public Health* for June is an article bearing on this matter, the author of which, Dr. Martin of Gorton, Manchester, England, treats especially of the connection between diphtheria and domestic animals, and quotes largely from different well-known writers in favor of this view. Dr. Longstaff, in a report on the Geographical Distribution of Diphtheria in England and Wales, said "The distribution of diphtheria and its mortality does not appear to be regulated by density of population, nor do insanitary conditions appear to favor its development," and he concludes his report thus: "The line of investigation which seems to me most promising lies in comparative pathology. The peasantry live on terms of great intimacy with domestic animals, more particularly with cows, sheep, pigs, poultry, and pigeons. Some little known diseases of some one or other of these creatures may be capable of inducing in the human subject brought into frequent and close contact with them a trivial 'membranous sore throat,' then, under suitable conditions of recipient and environment, the more generally recognized form of the disease, true diphtheria may result. The poison, perhaps, gathering intensity and infectiveness, may then be conveyed into towns by farm produce, such as milk, cream, poultry, eggs, meat, or vegetables, and, lastly, through the poisons first infected, the sources of water supply or the public sewers may get poisoned, and so indirectly aid in the spread of the disease." Dr. E. W. Goodall has described what he declares to have been an absolutely authentic case of diphtheria in a horse.

McFayden and Hewlett described in the throats of diseased and healthy pigeons an organism which resembled the Klebs-Löffler bacillus in morphological, cultural, and staining peculiarities, and differing only slightly in pathogenic and toxic properties. Roup, a malady which largely affects fowls, presents many features of marked similarity to human diphtheria. The writer of the article in *Public Health* states that diminution of cases of diphtheria, in his district, has been synchronous with regulations restricting the keeping of pigeons and poultry in backyards, while J. S. M'Intire brings forward the bold theory that cat-fleas may carry diphtheria to man, the cat being subject to a form of diphtheria, in the same way as it is argued by some that fleas carry the plague.

Dr. Martin concludes his article by drawing attention to the fact that the etiology of the disease points to some condition of home life affecting early childhood, decreasing after six years of age. Two animals are in close relation with the child at that period of life, namely, cow and cat, and both are liable to forms of diphtheria. Further it has been shown that varieties of diphtheria can be produced in pigeons and fowls by passages through other birds. Therefore, in the opinion of the writer, it is not difficult to conceive of a cat or a cow becoming infected, or to be the medium of conveying a pathogenic variety to human beings.

News of the Week.

Care of the Insane in New York.—Some of the measures of improvement in the care of the insane of the State of New York carried through during the past few months by the Lunacy Commission are as follows: The Pathological Institute has been reorganized and more than sixty of the medical men connected with the staffs of the fourteen State hospitals have been instructed during the past winter at the Institute on Ward's Island in the recent development of psychiatry along clinical pathological, psychological, and clinical lines. The hospitals have been opened to medical internes in the same manner as general hospitals. Last year sixteen clinical assistants entered the service in this way, and this year the number is nearer thirty. The Legislature recently passed the Lunacy Commission's bill for the appointment of a medical inspector to ensure a more thorough inspection of the thirty-nine institutions under its charge, viz., twenty-three private retreats, two criminal asylums, and fourteen State hospitals for the insane. To remedy overcrowding the Lunacy commission proposes to construct a new hospital in the territory north of Albany and Troy on the colony system. A scheme similar to that of the Craig colony for epileptics will be carried out. The site will be selected and plans made this year. It is hoped that this colony for 1,500 to 2,000 patients will be ready inside of three years. Three tuberculosis hospitals, each with a hundred beds, will be constructed this summer at a cost of $90,000 at Middletown, Utica, and Binghamton, on the grounds of the State hospitals located there; and the plans embody the main features of such hospitals described in the King Edward Prize Essays. Tent life for the tuberculous insane has been in vogue at the Manhattan State Hospital East (under Dr. MacDonald) for two or three years and for a shorter time at Binghamton and other of the State hospitals. The country colony for a few of the working classes of the insane, as an offshoot of the Utica State Hospital, has been enlarged. A similar colony has been established at the Willard State Hospital and two are in existence at the State hospitals at Binghamton and Poughkeepsie. A new departure this year is the creation of a summer camp for between forty and sixty insane on the lake shore about fifteen miles from the Rochester State Hospital, which is now in operation. The feature of nurses' homes having been found so useful at some of the hospitals, two additional ones will be put up this summer, one at King's Park State Hospital, Long Island, for three hundred nurses, and one at the Gowanda State Hospital for one hundred. Six or seven residences for superintendents and separate houses for the medical staffs will be put up this season at as many of the State hospitals,

thus removing the officials from the central main buildings and utilizing the vacated space for patients. A bill providing for emergency commitments, recommended by the Lunacy Commission, was passed by the Legislature at the last session. Copies of this law have been sent to all the examiners in lunacy of the State. It is believed that this will prevent the all-too-frequent incarceration of urgent cases of insanity in jails and station-houses. A strong effort is being made by the Lunacy Commission to increase the number of deportations of alien insane, and through the efforts of New York State the federal government passed a law making the limit three years instead of one, *i.e.* an immigrant becoming insane within three years after landing in the United States may be returned to his own country.

Protest against the Action of the Health Commissioner in the Antitoxin Cases.—At a mass meeting of physicians held under the auspices of the East Side Physicians' Club, June 12, 1903, Dr. Julius Solow presiding, the following resolutions were unanimously adopted:

"*Whereas*, A number of physicians practising on the East Side of the Borough of Manhattan have been arrested on warrants in criminal proceedings instituted by the Commissioner of the Health Department without previous notice, warning, or opportunity to present their defence of alleged charges of larceny in accordance with the best traditions of the Health Department, and

"*Whereas*, This hasty, unwarranted, and unprecedented aggressive action of the Department may tend to alienate the rank and file of the profession from their natural union and coöperation with the said department, and

"*Whereas*, The medical profession of this city as a unit has always stood ready to serve the Department of Health without fee or favor, be it

"*Resolved*, That the physicians of the East Side, in mass meeting assembled, deplore the circumstances and emphatically protest against the unmerited and summary procedure of the Department of Health, a procedure which demoralizes the community, offends the profession, and gravely injures the accused physicians and their families by branding them as common criminals, and be it further

"*Resolved*, That a copy of these resolutions be forwarded to his Honor, the Mayor of this city to the Commissioner of the Health Department, and to the press."—Signed, Dr. Julius Solow, President; Dr. I. Wm. Schapiro, Secretary.

Drs. Clarence A. McWilliams and Forbes Hawkes have been appointed Instructors in Surgery in the College of Physicians and Surgeons of Columbia University, New York.

The Stevens' Triennial Prize of Columbia University for original research has been awarded to Drs. L. Pierce Clark and Thomas P. Prout of New York upon "Status Epilepticus: A Clinical and Pathological Study of Epilepsy."

A Medical Protest against the Kishineff Massacre.—At a meeting of the Eastern Medical Society of this city, held June 12, resolutions were adopted deploring the massacre of Kishineff and protesting against the renewed outbreak of persecution of the Jewish inhabitants of Russia, which has been made possible by the culpable neglect of the government. The resolutions call for the exercise of the good offices of the United States Government in obtaining from the Russian Government better protection for its citizens of the Hebrew race. The following are the members of the executive committee signing the resolution: Drs. A. E. Isaacs, A. Rovinsky, D. Robinsohn, J. Barsky, and Z. Scharfin.

Organization of the Louisville Academy of Medicine.—On Wednesday evening, June 3, 1903, at the Louisville Hotel, the Practitioners' Club and the Falls City Medical Society met and amalgamated, forming the Louisville Academy of Medicine, with twenty-eight members present. The following officers were elected: *President*, Hugh N. Leavell; *Vice-President*, John J. Moren; *Secretary*, Hugh R. Manning; *Treasurer*, Dr. W. A. Jenkins. A paper on "Tumor of the Kidneys" was read by Dr. Charles G. Lucas, who exhibited a pathological specimen, removed at postmortem.

Foot-and-mouth Disease.—The Secretary of Agriculture, having completed a careful investigation of the States now in quarantine for foot-and-mouth disease, through the inspectors of the Bureau of Animal Industry, without finding any cases of the disease during the last five weeks, has offered a reward of $250 for all cases, in either Massachusetts or New Hampshire, that are reported prior to July 1. The nature of the disease must be confirmed by the inspectors of the Department. The object is to ascertain with all possible certainty that the disease has been entirely eradicated, before the quarantine is removed and foreign countries are asked to receive again live stock from New England ports. It is believed that the disease has been entirely eradicated, and this reward is offered as a final effort to discover any traces of contagion that may possibly exist.

Suit of an Opera Singer against a Physician.—A well-known opera prima donna of Munich, Mme. Mikla Ternina, has brought suit for 50,000 marks against her physician. She suffered severely from trigeminal neuralgia and, while under treatment for the same, became partially paralyzed in the left side of the face. She was led to believe that the remedies employed for the neuralgia brought on the paralysis.

Tri-County Medical Society of South Jersey.—A society with this name was organized on May 27, at Woodbury, N. J., at a meeting of physicians for the counties of Cumberland, Salem, and Gloucester. The following officers were elected: *President*, H. A. Stout, Wenonah; *First Vice-President*, B. A. Maddington, Salem; *Second Vice-President*, N. W. Elmer, Bridgeton; *Secretary* and *Treasurer*, George Evans Reading, Woodbury; *Executive Committee*, L. M. Halsey, Williamstown; E. E. DeGrofft, Woodstown; and D. Oliver, Bridgeton.

Alabama State Medical Association.—At the annual meeting of this society at Talladega, the following officers were elected: *President*, M. B. Cameron of Sumpterville; *Vice-President*, J. R. G. Howell of Dothan; *Secretary*, Lewis C. Morris of Birmingham; *Treasurer*, H. G. Perry of Greensboro. The annual meeting for 1904 will be held in Mobile.

Mississippi State Medical Association.—At the annual meeting of this society at Vicksburg, the following officers were elected: *President*, C. D. Mitchell, Pontotoc; *Vice-Presidents*, Joseph Waldauer, Vicksburg; May F. Jones, Columbus; B. L. Culley, Jackson; *Secretary*, J. J. Haralson, Forest; *Treasurer*, Dr. J. F. Hunter, Jackson. The annual meeting for 1904 will be held at Pass Christian.

American Congress on Tuberculosis.—At a conference of the officers and Advisory Committee of the American Congress on Tuberculosis, held in New Orleans, May 7, some important changes were made in the plans as previously announced. The previous plans of the Council to hold the congress in St. Louis, in 1904, were changed, many considerations favoring Washington, D. C., as the place of meeting. A change of time of meeting was also

made to April, 1905. The change in date was made so that there should be no interference with the International Congress on Tuberculosis which is to be held in Paris in 1904. A committee was appointed to have charge of the Section on Pathology and Bacteriology, as follows: Dr. Simon Flexner, Chairman, Drs. William H. Welch, George J. Adami, Theobald Smith, and F. F. Wesbrook.

A Birth Benefit Company.—The American Mothers Association of the United States has organized what it calls a "birth insurance society," for the benefit of its members who justify their title to membership by becoming mothers. The monthly dues are only $3, and the payments made to the policy-holders giving birth to a living child are from $200 to $500, according to the length of time during which the monthly premiums have been paid. The benefits are restricted to associate and junior associate members of the Mothers' Association, and the only restriction is that "no person shall receive any benefit for a birth which occurs within nine months from the date of payment of the first regular assessment," which is probably of the nature of the suicide clause in the older life policies and intended to discourage attempts to beat the game.

Dr. Frederick E. Lambert of Jersey City has been appointed trustee of the City Hospital to succeed Dr. John J. Baumann who resigned recently.

Decision against the State Veterinary Examiners.—A case which may have an important application in the interpretation of the medical practice law of this State has recently been decided in Troy. The State Board of Veterinary Examiners refused to accept as satisfactory the testimony of an applicant for license that he had practised veterinary medicine for three years prior to the year 1900. The applicant carried the case to the courts, and Justice Howard, in Special Term, at Troy, has decided that the Board must recommend the issue by the Regents of a veterinarian certificate to the applicant, accepting his affidavit as sufficient evidence of previous practice.

A Suit for a Stomach.—A Milwaukee surgeon, performed a gastrectomy on a woman some time ago and kept the part removed among his pathological specimens. The son of the woman has now sued the surgeon for $5,000, the alleged value of the purloined stomach.

Drug Inspections in Massachusetts.—At the recent annual meeting of the Massachusetts State Pharmaceutical Association a resolution was passed protesting against the action of the State Board of Health in inspecting, from time to time, the stocks found on the shelves of the retail druggists. Some of the examinations of drugs, like those made in New York and other cities, had shown that the crime of adulteration and substitution of drugs was by no means uncommon.

The Indiana State Medical Society.—At a meeting of this society held at Richmond, on June 4 and 5, the following officers were elected: *President*, Jonas Stewart of Anderson; *Vice-President*, Chas. A. White of Danville; *Secretary*, F. C. Heath of Indianapolis; *Assistant Secretary*, C. T. Hendershot of Connelton; *Treasurer*, A. E. Bulson, Jr., of Ft. Wayne.

Obituary Notes.—Dr. Isaac Newton Love of this city, recently of St. Louis, died of apoplexy on the steamship *Aurania* as the vessel was entering New York harbor on the morning of June 18. He went to Paris with a patient about a month ago and returned by way of Liverpool. The voyage was a pleasant one and Dr. Love was apparently in excellent health and spirits and was the life of the ship. He was at breakfast and presiding at a meeting which had been called to present congratulatory resolutions to the captain when he fell to the floor and died immediately. Dr. Love was born in Barry, Pike County, Ill., in 1848. When thirteen years old he went to St. Louis to live in the family of a relative, Dr. John T. Hodgen, who was a famous surgeon. He studied in the St. Louis high schools, and in 1872 he received the degree of M.D. from the old St. Louis Medical College of the Washington University. He was the city physician of St. Louis for a time. He devoted special attention to the diseases of infancy and childhood. In 1887 he was made president of the Mississippi Valley Medical Association. In 1889 he was elected president of the section of diseases of children of the American Medical Association, and also one of the trustees of the *Journal of the American Medical Association*. That year, also, he was chosen president of the American Editors' Association. In 1890 he issued the first number of the *Medical Mirror*, of which he continued as editor after his removal to New York, although the publication office is in St. Louis.

Dr. John C. Halstead of this city died at his home on June 17 of tuberculosis of the bladder. He retired from active practice several years ago on account of ill health. He was born in Harrison, Westchester County, and was graduated in medicine at the New York University in 1883.

Dr. Orpheus Everts of Cincinnati died on June 19 at the age of seventy-six years. He was a graduate of the Indiana Medical College, Laporte, in 1848, and received a second degree from the Rush Medical College, Chicago, in 1867. He had been superintendent of the Cincinnati Sanitarium since 1880, and was a member of the American Medical Association, the Mississippi Valley Medical Association, the American Medico-Psychological Society, the Ohio State Medical Society, and the Cincinnati Academy of Medicine.

Subcutaneous Injection of Paraffin.—Kofmann utters a word of warning against the indiscriminate employment of Gersuny's method of prosthesis by this means. He himself carried out the technique with great success in a number of cases of saddle nose, depressed scars, and even for deformity following amputation of the breast, when he undertook to apply it for the correction of a slight prolapse of the uterus. Two injections had been made through the same puncture, and the syringe was being emptied for the third time when the patient suddenly began to cough, and within twenty-four hours was dead of pulmonary embolism. The author, therefore, warns against using this procedure in gynecology, and in any region of the body where anastomosing vessels are numerous and advocates the routine use of a paraffin, having a melting point of 57-60° C, injected from a syringe inclosed in a non-conductor of heat.—*Centralblatt fur Chirurgie.*

Neurasthenia in Children.—Luigi Cappelletti gives the various symptoms of this disorder, but considers that the absolutely characteristic symptom is a special attitude of the mind, which he calls a state of doubt. The children are in a continual condition of hesitation, which leads to inability to finish work, as in school, a tendency to isolate themselves from their playmates because their constant hesitations put them out of tune with their more lively and decided companions, and a general morbidity of character, with a tendency to analyze their sensations and motives. Such a condition of doubt should arouse the attention of the physician, who, by prescribing special treatment for the development of energy and resolution may avert life-long suffering to the patient.—*La Riforma Medica.*

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL; THE CONTROVERSY WITH THE COLLEGES; FINANCIAL DIFFICULTIES—ROYAL MEDICAL CHIRURGICAL SOCIETY—PHENOMENA OF DROWNING AND RESUSCITATION OF THE APPARENTLY DROWNED—DEATHS OF DRS. HAVILAND, D. JONES, AND DELLER.

London, June 5, 1903.

The Medical Council came to no conclusion as to its dispute with the two royal colleges. You will remember I gave you an account of the matter last year, so far as it had then progressed. It has been drifting ever since, but whether these august powers will drift into war remains to be seen. At present there is a sort of truce. The council disapproves of the action of the colleges in recognizing school teaching in chemistry, physics, and biology as a part of the five years' curriculum. The colleges have recognized thirty-four secondary schools as places of study in these subjects, and say if the preliminary examination has been passed, and the equipment of the schools is up to date, prolongation of study at these schools is better for boys than too early entry at hospitals.

The council had before it the report of the Education Committee, which states that any period from three months to a year passed in study of one, two, or all three of the above subjects, at these secondary schools, is permitted by the colleges to count as part of the five years' curriculum. But the report also says that in the majority of these schools biology is not taught at all, and the instruction in physics and chemistry occupies less than fifteen hours a week—in many much less. It seems actually possible for six months of the curriculum to be constituted by a course of chemistry and physics limited to four or five hours a week, taken out at an ordinary grammar school during school hours, or at a technical institute's evening classes.

The colleges are inclined to stand on what they hold to be their legal right to regulate their curriculum.

The council has no means of enforcing its view short of representing to the Privy Council that the course of study of the conjoint board of these two colleges is not sufficient. Sir Victor Horsley would do this and would no doubt be supported by most reformers, but the council hesitates as usual at any decisive action "letting I dare not wait upon I would." Result—resolution to hold a special meeting in July to consider this and other reports on examinations not yet to hand.

This extra meeting will, of course, entail extra expense, and the next important subject taken up was the financial position of the council. The report on the careful memorandum of the president on this matter suggesting that the council should receive a grant in aid, as the Incorporated Law Society does, was brought up and discussed. On this I remark that the lawyers are strong enough in the House to enforce their claims to consideration, which is not the case with us.

Some councillors objected to asking money from the government lest unpleasant conditions should be imposed. One expressed an opinion which is pretty general outside but did not seem welcome within, that the council did not manage its business properly, and gave too much attention to things which would be as well let alone. Another said that as trustees they ought to avoid extravagance on one hand and niggardliness on the other. The old political cry of "Peace, retrenchment, and reform," was quoted, which provoked the more modern cry of "efficiency."

Sir V. Horsley proposed to reduce printing bills, traveling allowances, and other items. These suggestions were well received—not so a further one to prolong the sittings for an hour a day.

These hard-worked gentlemen could not curtail their time of amusement in their jaunts to London. Four hours in the council room was declared by one member to be fatiguing enough at a time. The atmosphere is certainly rather close. Eventually it was agreed, by a majority, to ask for a government grant.

In 1892 the Royal Medical and Chirurgical Society appointed a committee to inquire into the phenomena attending death by drowning, and the means of promoting resuscitation in the apparently drowned. The report of this committee was presented by Professor Schäfer at the last meeting. A former committee of the same society in 1862, reported in favor of Silvester's method, and that became almost universally employed, but it seemed that further investigation was desirable, and so the society appointed the last committee. The report gives an account of some physiological experiments and also experiments designed to measure the amount of air taken into or forced out of the lungs by the various methods of artificial respiration, following thus the lines of the 1862 report. No less than ten different methods were tested, all of which proved competent to effect a sufficient exchange of air to maintain the oxygenation of the blood. The smallpox amounts were given by the plan of simple traction by both arms, the subject being supine. Rolling the subject alternately from the lateral or latero-supine to the prone position, with alternating pressure upon the back of the thorax was very effectual. The pressure applied to the back was more evenly distributed than otherwise, and simple rhythmic pressure in the prone position was recommended for a prominent place in directions for the resuscitation of the apparently drowned.

The experiments showed the great length of time immersion might occur and recovery follow—in one case eight minutes. In other cases a much shorter immersion was followed by death in spite of artificial respiration; in two cases, in spite of the reëstablishment of natural respiration. Sometimes this was due to heart failure, sometimes to deficient aeration of the blood by the respiratory movements. The amount of frothy mucus seemed to have an important influence. Sea water gave less rapid results than fresh water. The injection of suprarenal extract to antagonize the lowering of blood-pressure had a very transitory effect. These are only some of the points in this report, which is deserving of attentive study.

In the discussion that followed, Dr. Silvester said the committee had not followed exactly his method, as they had not placed the body on an inclined plane, which was essential. The rolling method was likely to force the contents into the pharynx, whence they might pass into the air passages. He thought the report rather retrograde. He thought experiments on animals under anæsthesia were not altogether comparable to cases of accidental drowning.

Dr. R. L. Bowles expressed the same opinion as to anæsthetics, and said the condition of the lungs in dogs drowned experimentally differed from that found in man. The supine position let the tongue fall back, which, with the mucus in the pharynx, hindered the artificial respiration. He held that the public should be taught only one method—and that Marshall Hall's.

Dr. Woods said that the first thing was to get rid of the water from the lungs, and the prone position was the one for that. Often too little pressure on the back was employed.

Dr. Hewitt compared death by drowning and anæsthetics. Often spasm prevented the entrance of air. Perhaps the inflation method might meet such cases.

Dr. Pembey attached very little importance to the amount of air forced into the lungs, as a few extra respirations made up the deficiency. The influence of the nervous system could not be overlooked in man.

Mr. Alfred Haviland died on the 30th ult., aged seventy-eight years. He was deeply interested in climatology and meteorology as connected with the distribution of disease, and wrote many papers on such subjects. At one time he lectured at St. Thomas' Hospital on the geographical distribution of disease. His work on the distribution of cancer and phthisis in 1875 produced a great impression. He had written on climate and weather twenty years before that, and he has continued his work to the end of his life. The article on medical geography in Allbutt's System being from his pen, and he gave an inaugural address on this subject as an aid to clinical medicine in 1897. For nearly three years he has been incapacitated by illness.

Dr. David Jones died on the 20th ult., at the age of seventy-six years. He practised for about forty years in a suburb of Liverpool.

In contrast with this, Dr H. G. Deller did not enter into practice at all, but was cut off by phthisis after a brilliant career at Cambridge, where he took his M.A., M.B., and B.C. He also took the diplomas of the two colleges (1898). He went to South Africa to try the effect of climate—afterward to Davos Platz, where he died on the 26th ult., aged thirty-one years.

The Diagnosis of Meningeal Hemorrhage.—Fernand Widal says that at the present time this disease is one of the affections the diagnosis of which is the least difficult to establish. Kernig's sign indicates the meningeal lesion, and lumbar puncture by demonstrating the presence of blood in the spinal fluid furnishes the proof of the hemorrhagic nature of that lesion. The nature of the blood found in the fluid is of importance in the diagnois, nor is it an easy matter to decide as to its source. A careful study must be made of the intensity of coloration, the coagulability of the fluid, and the variations found in the fluid obtained by several punctures.—*La Presse Médicale*, June 3, 1903.

OUR LETTER FROM THE PHILIPPINES.

(From our Special Correspondent.)

THE PROBLEM OF SAN LAZARO HOSPITAL—LEPROSY IN THE PHILIPPINES—PROSTITUTION IN MANILA—SANITARY EXAMINATION OF PROSTITUTES—DETENTION CAMP FOR CHOLERA, SMALLPOX, AND PLAGUE SUSPECTS—CONTAGIOUS DISEASE HOSPITAL—THE MANILA CITY MORGUE.

MANILA, APRIL 28, 1903.

ABOUT a mile from the business section of Manila is located the San Lazaro Hospital, a large, rambling old pile, built some three centuries ago, and inherited from the former Spanish administration here. It is a two-story structure, built around a central court and having projecting wings. The buildings are of stone, with enormously massive walls many feet thick, pierced by infrequent and small, grated windows, and altogether the architectural effect is more like that of a fortress or a dungeon than a hospital. The basement rooms are low, dark, damp and poorly aired, the water supply is insufficient, and the little plumbing and sewerage provided is poorly planned, badly constructed, and in worse repair. The whole institution is something of a white elephant on the hands of the health authorities, as much money has been expended on it by the Spaniards, and the buildings are strong and substantial to the last degree, having withstood the ravages of time and the earthquakes of three hundred years with little injury. It would seem desirable, if possible, to utilize these buildings as far as practicable, in the interests of economy, yet their plan, arrangement, and construction are such that they would have to be so extensively altered and remodeled that it would probably be as cheap, and certainly more satisfactory, to abandon them entirely to other uses and build a new hospital elsewhere. Unfortunately, the buildings are so located and planned as to be of little value except as a penitentiary or for storehouses, and there is no present necessity for either. A government hospital for the insane is much needed, and it has been proposed to put these buildings to that use, but they are thoroughly unsuited for such a purpose. At present the hospital shelters about 200 lepers in one-half of its buildings, and about the same number of prostitutes affected with venereal diseases are held for treatment in the other part of the institution. With the completion of the buildings for the leper colony on Kulion Island in the next few months, the lepers will be removed. The authorities will then have to decide whether the disinfection of the leper buildings is practicable by ordinary measures. These buildings have sheltered several hundred lepers constantly for three centuries, and are certainly thoroughly infected with the lepra bacillus throughout. While the characteristics of the latter have not been thoroughly worked out, it is known to be strongly resistant to drying and to retain its virulence for a long time under such conditions as prevail in the San Lazaro institution. Where everything is so saturated with infectious material, it is probable that all the woodwork should be torn out and burned. The stonework would have to be thoroughly scraped down and plastered over, the present windows must be enlarged and new ones cut, and this would be extremely expensive. After all necessary work had been done only a mere shell would remain, and this would even then be unsuited for hospital purposes. The ground on which the hospital is situated is so flat that there could be no flow of sewage into a distant "estero" without the use of pumping, and the soil is scarcely of the proper character to make its disposal by means of sewage farming a success, and in the wet season the water stands in pools all over the surrounding flat country. For these reasons the problems raised in connection with the remodeling of these old buildings are very serious. The whole institution is enclosed by a high stone wall, and the enclosed space is further divided into smaller areas by division walls. The detention camps for cholera, plague, and smallpox contacts being located in one of these spaces.

The type of disease presented by the lepers in the hospital is chiefly of the tuberculous form, and few of the cases appear to be far advanced. Mutilation of the extremities seems to be infrequent, and the horrible disfigurations so common in the lepers seen in the countries of Spanish America are relatively rare here. The sexes are about evenly divided, and a large number of the patients are children. A native Filipino doctor is in direct charge of these unfortunates, who are nearly all Filipinos. There are two or three Chinese lepers, but no whites. The lepers appear to be cheerful and contented, though a half dozen are said to have escaped when they were informed of their probable early removal to the leper colony on Kulion They have their own theater, chapel, and school. Those less affected perform all the work for the leper hospital, for which they receive the same pay as the attendants in the women's department of the hospital The cooks are leprous, and order is maintained by several lepers who are paid to perform police duty and who seem very proud of their authority, uniforms, and policemen's clubs. The money that the lepers receive for their services they use to purchase delicacies, and to send to their friends and families outside. The institution is as neat, clean, and well kept as the faulty arrangement, construction, and lack of modern sanitary conveniences permit, and there is no overcrowding. There is no communication between the leper department and the rest of the institution, except through the physicians in charge.

The cases of leprosy presented seem to be of an unusually slowly progressive type. Treatment is purely symptomatic; the various specific treatments have been tried and found wanting. Only a few of the patients are in such condition as to require frequent medical attention. The good results reported from the use of the *x*-ray and the Finsen ray in lupus and the treatment of neoplasms has induced the authorities to order the necessary apparatus for a thorough trial of these methods of treatment; the apparatus has not yet arrived and probably will not be installed at San Lazaro but sent direct to the leper colony on Kulion Island.

The women's department of the hospital at present contains about 200 prostitutes affected with venereal disease, of whom 100 are Filipinos, 85 are Japanese, and the remainder are white—chiefly Russians. There was one American. There are between 400 and 500 prostitutes living in the municipal district in which they are segregated in Manila, and of these about one-half are at present diseased. The women's department at San Lazaro is at present filled to its utmost capacity, and a few prostitutes are consequently receiving treatment outside. The known prostitutes are, as already mentioned, segregated in a certain district of the city, as far as possible, and are kept under sanitary supervision. They are not licensed or registered, but are now examined by a city physician at intervals of about one week, and smears are made from each individual at the time of examination, marked by name and sent to the Government Laboratory for microscopical examination. This microscopical test reveals many cases of gonorrhœa which would otherwise be passed over If a woman is found to be diseased, the case is reported to the police, who order the woman to enter the hospital for treatment, under the municipal laws governing the control of contagious diseases, by the health department. After entering the hospital the woman is kept there until cured —in the case of gonorrhœa, she is kept there until smears made for several consecutive days, from the urethra and from the cervix, fail to show the presence of gonococci on microscopical examination. It not infrequently happens that this test remains positive for some time after the gross visual signs of the disease have disappeared. Gonorrhœa is by far the most common disease among the public women, especially among the Japanese prostitutes, who seem to have a special resistance to syphilitic infection. Chancroids are relatively much more common among the Filipinos than other nationalities. Syphilis is relatively rare among all these women. The examinations at the hospital are conducted by the two physicians attached to the department, one of which is an American and in charge of the whole San Lazaro institution. They verify conditions, make the microscopical specimens and prescribe the treatment: the latter being given by the native female nurses attached to the institution. Gonorrhœal cases receive two vaginal injections daily, potassium permanganate or benzozone solutions being commonly used. Chancroids are cauterized and treated antiseptically—the local application of a paste of benzozone crystals to the lesion is said to have given very excellent results in many cases. The usual treatment is followed in respect to syphilis. A row of reclining tables and siphon bottles of solutions enable the douches to be given quickly and effectively. A matron and the female nurses preserve order. The women are very quiet and orderly and make little trouble. The Japanese are especially tractable. The Filipinos occasionally disagree among themselves. The white prostitutes chafe more under the restrictions and the few of them make more trouble than ten times their number of Japanese and Malays. One recently attempted to take out *habeas corpus* proceedings, but was informed that if she were successful she would be arrested and sent to Bilibid prison under the laws governing vagrancy—which alternative has operated to prevent further attempt at recourse to the courts. The food is good, well cooked and of ample variety, costing about forty-five cents Mexican per day. It is better than anything that the Filipinos and Japanese are accustomed to eat. The white prostitutes are fed on a somewhat better scale, to avoid too much complaint, as they have usually been accustomed to living well.

The entire expenses for treatment and subsistence are borne by the Government, and the women have no expenses from the time they enter the hospital until they

leave it. As the system is operated, there is no attempt to create any official recognition of vice or the licensing of prostitutes. The women are regarded from exactly the same sanitary standpoint as suspects or contacts with bubonic plague, smallpox, or cholera would be regarded, and, like the latter, they are examined from time to time to ascertain if the suspected disease has developed. Should the latter be the case, they are isolated and given medical treatment like any other individuals affected with a dangerous communicable disease. The whole thing is a practical sanitary proposition and is handled as such, any abstract questions of the immorality of prostitution not entering into consideration as having no relation to the public health. The system is not as perfect as could be devised, but is efficient so far as it goes. The unfortunate women receive good care and medical treatment, and are themselves much benefited thereby, while the enforced isolation of some two hundred cases of communicable disease cannot fail to have a pronounced and markedly favorable effect upon the public health. In few cities in the United States is the delicate sanitary question of prostitution in relation to venereal disease handled as well as here. The women, especially the Japanese, rarely leave their houses, or appear on the streets, and when they do they conduct themselves in public in such a manner as to attract no attention and give rise to no offence. Such a thing as solicitation, so common in New York and other large home cities, is practically unknown here. As the system is operated under local municipal laws, it is fortunately beyond the reach of the professional reformers at home. A stricter system prevails in some of the towns of the Southern islands, where venereal disease, by rigorous inspection and control, has been rendered as rare among the public women as it is common among the prostitutes of the United States. While on this subject, it may be mentioned that there is little venereal disease in the country districts, except what is imported. This is explained by the fact that outside of the cities there is little public prostitution, and this, in turn, is influenced by the existence of a general system of concubinage among the natives, in which the Filipino public sentiment sees no harm. The native women are *un*moral rather than *im*moral. Many of them live with a man, bear him children and remain true to him for the sake of a mere subsistence where they would repudiate the idea of general prostitution for purposes of gain. Such women lose no prestige among the lower native classes because of the position they occupy. If such a woman becomes infected with venereal disease, the chances are extremely small that she will communicate it to others of the opposite sex, and for this reason the proportion of such disease in the smaller communities is relatively small.

It is expected that the present more searching and scientific methods of examination of prostitutes in Manila will greatly reduce the amount of venereal disease among them. Until very recently the system of inspection practically existed in name only. A native physician was in charge of the matter, and his work was not at all satisfactory. Microscopical methods of diagnosis were not used by him. When he was relieved and an American physician, lately, put in charge, the amount of venereal disease among the prostitutes was found to be six or eight times greater than was reported by the Filipino doctor previously in charge. The system of inspection and isolation must be conscientiously and scientifically carried out by competent men—when it is so carried out it is of very great sanitary value. The arguments urged against the system by its opponents with respect to its sanitary inefficiency do not apply where the work is as thoroughly done as has lately been the case here. No harm is done thereby and much good results. One American female reformer recently objected to it in a newspaper interview, on the ground that the examination "humiliated" the prostitutes, but this objection would not seem to apply to a class that is ready at any time to be "humiliated" for the sake of gain.

Within the main walls surrounding the San Lazaro hospital, occupying a large enclosed space, is located the detention camp for contacts with cholera, smallpox, and plague cases. The buildings are of bamboo, with nipa thatch roofs, and are elevated several feet above the ground. They consist of long pavilion buildings, divided into small rooms by walls of bamboo, the latter reaching nearly to the ceiling. Each room has its own door and is intended for the shelter of a family. The camps, as a whole, may be capable of accommodating a thousand persons. The buildings are not at all suited for the purpose for which they are intended, inasmuch as they are built of porous and retentive material, and if once infected, their disinfection would be most difficult. They were hastily constructed on the sudden outbreak of cholera, when there was neither money nor opportunity for the erection of structures of more desirable type and material. At present their capacity is largely in excess of the needs of the city, but this excess may be of much advantage should the anticipated recrudescence of cholera occur with the beginning of the rainy season. As the life of buildings of bamboo and nipa is but a short period at the most, the detention camp will have to be rebuilt within a few years. By that time the future of San Lazaro Hospital will have been decided, and solidly constructed buildings for a permanent detention camp can be leisurely erected on the present site or on some location elsewhere.

The contagious disease hospital, with detached wards for smallpox, cholera, and plague, is located on the other side of San Lazaro hospital, outside its walls and some 600 yards from the detention camp. The buildings are poor, and their arrangement, capacity, and location are unsatisfactory. They are on a well-traveled road and there is a cluster of native houses only a short distance away. The hospital buildings are not fenced in, and there is no way of preventing a certain amount of communication between the native employees and those outside. The authorities are planning to remove the entire establishment inside the San Lazaro walls, and in the meantime have ordered the road closed and the contagious disease hospital enclosed by a high board fence. At the present time the hospital contains eighteen or twenty smallpox cases and eight or ten of plague.

The best sanitary feature of the San Lazaro establishment is the new city morgue, which is now being constructed on one edge of the San Lazaro grounds. This is a permanent building of wood and iron, and is fitted up in a thoroughly sanitary, though inexpensive, manner. There are no facilities for the preservation of bodies, and the latter will be sent to the morgue only for a few hours' stay, for the performance of autopsies, and to provide for their final disposition. The bodies of the unclaimed dead and those dead from plague, cholera, and smallpox are disposed of by cremation, except in the case of Americans and Chinese, the bodies of whom are buried after being packed in quicklime and enclosed in hermetically sealed metal caskets. The city crematory, where the bodies are incinerated, is also located on the San Lazaro grounds. It is fitted up as a general crematory, and much combustible refuse, carcasses of animals, etc., are destroyed therein. Thus, during the month of January past, there were 3,046 carcasses of animals and 1,819 loads of refuse destroyed by cremation. A small disinfecting plant is now being set up near the detention camp, for use in connection therewith.

Progress of Medical Science.

The Boston Medical and Surgical Journal, June 18, 1903.

A Case of Paget's Disease of the Nipple Treated by the X-Ray.—Edith R. Meek reports the case of a colored woman, aged thirty-two years, suffering from Paget's disease of the nipple. Operation was advised and refused. *X*-ray treatments were given. Within ten days marked improvement was noted; at the end of the fourth week the nipple and areola were perfectly normal in appearance. At the beginning of the sixth week microscopical examination was made with the report of normal skin and subcutaneous tissue.

Hæmostasis by Compression and Heat.—John W. Keefe states that his experience with the Downes' electrothermic angiotribe has convinced him that he can dispense with the use of the ligature—certainly to a great extent, if not wholly. He reports a series of 50 cases in which the electrothermic angiotribe was used; 45 cœliotomies, 13 abdominal hysterectomies, 2 salpingo-oophorectomies, 28 appendectomies, 2 ovarian cysts, 1 resection of intestine, 1 nephrectomy, 1 amputation of thigh, 1 amputation of leg, 1 varicocele, 2 hemorrhoids, 1 removal of Meckel's diverticulum, 1 ruptured tubal pregnancy, 2 vaginal hysterectomies. The instrument perfected by Downes, known as the electrothermic angiotribe, is unquestionably of practical value, as shown by the results in the foregoing cases, no secondary hemorrhage having taken place. The femoral was clamped in a thigh amputation and the anterior and posterior tibials in an amputation of the leg. The writer found the clamp useful doing a gastroenterostomy. He speaks of the most interesting case to him as that of the resection of fourteen inches of the intestine on a man, following numerous experiments on dogs. The author sums up the advantages of the use of the electrothermic angiotribe as follows: the exclusion of the ligature, hæmostasis *en masse* or of isolated blood vessels, aseptic gastrectomy, gastroenterostomy and resection of intestine, appendectomy, salpingectomy, extension of septic material during operation being rendered impossible, sterile occlusion of the Fallopian tube, absence of irritable and painful stumps, less tendency to post-operative adhesions, rapidity of operation, no secondary hemorrhage from

slipping of ligatures or suppurating sinuses due to ligatures, less pain subsequent to operation, and no puckering or dragging on the tissues. It is of special value in removal of cancer, as there can be no danger of inoculation, with cancerous material during the operation, and the heat destroys the cancer cells beyond the point of application of clamps.

Journal of the American Medical Association, June 20, 1903.

Prolonged Withdrawal of Food in Certain Cases of Intestinal Disorder.—T. D. Parke advances two propositions: first, that infants can be safely deprived of all food except water for much longer periods than have been formerly advised, and, second, that in the management of severe cases of intestinal disorder, this withrawal is of the greatest therapeutic value. He records the case of an infant of ten months with ileocolitis, who for five days was kept on water alone, baths being used to reduce temperature. At the end of this time three ounces of albumin water were given, but all the symptoms were aggravated by it, and recourse was again had to the water diet for three days longer. At this time the fever abated, the stools changed, diluted food was given, and the child went on to recovery. Parke notes that children under this method do not emaciate as much as might be supposed. It is not to be tried indiscriminately, and his contention is that not time but the character of the stools and the general condition of the patient should be the rule for the return to food.

Aphthæ and Herpes Contracted by Children Drinking Milk from Cows Suffering from Foot-and-mouth Disease.—E. F. Brush reviews the histories of several epidemics of the source and nature indicated by the title of his paper, and appends abstracts from the literature of the subject. He notes that there is an aphthous condition of the young in both the bovine and human families that is non-contagious, and there is also an aphthous condition in both these species that is contagious, and the similarity between the contagious and the non-contagious in both families is so marked, clinically, that it is very difficult to separate them; in neither of the families and in neither the contagious nor non-contagious affection has, up to the present time, any pathogenic organism been discovered, and in the contagious affection, contrary to the general rule, one attack does not give immunity. Therefore, the only way to diagnose in the human young a stomatitis aphthosa acquired from the bovine race would be from a knowledge that the milk comes from an infected herd. All the literature points straight to one fact, namely, no matter how severe the affection may be, if it is caused by the milk it subsides very quickly without further treatment by simply stopping the milk. So it follows that the simplest way to diagnose between contagious and non-contagious stomatitis aphthosa in the milk-fed young is to stop the milk. Then, if the milk was the cause, the diagnosis is made and the affection cured.

Management of Catarrhal Pneumonia in Infants.—C. G. Kerley notes that at the commencement of the disease every child has a definite resistance with which to withstand the disease. Every unit of this must be conserved by treatment. Irritability, restlessness, and loss of sleep are tremendous forces against recovery. Special attention must be paid to ventilation. The patient must not be over-clothed. The oiled-silk jacket is useless and even harmful. Food should be reduced to from one-third to one-half by dilution with water, so that the quantity given remains the same. Children from two to four years may have diluted milk, gruels, and broths. The patient should not be disturbed oftener than once every three hours, and at such time all the nursing offices should be performed. The bowels should act once daily. Kerley places great reliance on steam inhalations and mustard plasters for counterirritation, but very definite directions must be given for the latter, else they will probably be of very little value. Hot mustard baths are useful in cases with a sudden invasion, high fever, rapid breathing, and cold extremities. Internal drug treatment is to a large extent symptomatic. Cough syrups should be avoided. The necessary remedies can be given in tablet or powdered form. The ammonia salts are useful during resolution, but should not be given as a routine measure, for they are apt to upset the stomach. Tartar emetic and ipecac form a valuable combination. For reduction of fever, if bathing cannot be carried out or does not prove efficient, we may give caffeine, Dover's powder, and phenacetin. Heart stimulants are called for when we see that the heart needs assistance but not before. Tincture of strophantus is the author's favorite drug for this purpose. Strychnine may be added to the strophanthus if necessary. Alcohol is to be avoided unless other means fail. In cases presenting cyanosis with cold extremities nitroglycerin may be given. In severe cases with restricted breathing space oxygen may be used. As a general all round antipyretic measure, the author advises the cold pack. Properly applied, it is free from all danger. In conclusion, he states that in catarrhal pneumonia the administration of drugs is of secondary consideration. We first make the child comfortable, place him under proper diet and hygienic rules of living, use local applications, steaming, and means other than the internal use of drugs, when possible. When drugs are given they should, without compromising their efficacy, be made as innocent as possible.

The Medical News, June 20, 1903.

A Contribution to the Pathology and Prognosis of the Diseases of the Bladder.—Robert Holmes Greene and Harlow Brooks conclude: (1) The most frequent cause of diseases of the bladder is: (*a*) Lesions of the central nervous system, causing dilation, (*b*) septic processes of various varieties, (*c*) hypertrophy of the prostate. (2) In all conditions in which the spinal cord or central nervous system is involved, frequent and early catheterizations should be resorted to, to prevent the bad effects of overdistention, or the possibility of cystic rupture. (3) Conditions of the bladder must greatly modify the prognosis in operative proceedings for the relief of obstructions of the urinary flow, therefore the importance of cystoscopic and other examinations cannot be too strongly insisted upon. (4) Hypertrophy of the bladder wall is due to four different processes, separate or combined: (*a*) Inflammatory infiltration, (*b*) increase of the fibrous connected tissue, (*c*) smooth muscle hyperplasia, (*d*) infiltration by new growth. The clinical symptoms in hypertrophy of the bladder depend on which of these factors predominate.

New York Medical Journal, June 20, 1903.

Whooping-cough; a New Method of Treatment.—The new method referred to in this article by T. W. Kilmer consists in the application of a stockinette band placed on the patient in the same manner as is done in orthopedic surgery preparatory to applying the plaster jacket. Shoulder straps prevent the band from slipping down. Upon this stockinette a single width of elastic bandage is sewed, extending entirely around the body and covering the abdomen. The bandage is fastened on slightly on the stretch. To this apparatus Kilmer attaches the greatest importance as a preventive of obstinate vomiting, especially in nurslings. This prevents inanition and often saves life. A similar band around the chest will often abort the paroxysms of coughing. In some instances a slight eczema is caused, but this clears up as soon as the belt is removed.

Pertussis with Unusual Cerebral Symptoms.—E. E. Graham reports the case of a child aged nineteen months. She had been suffering with pertussis for two months, and three weeks before coming under observation, became dull, apathetic, and finally stupid. She gave constantly low moans and moved the arms and legs but slightly. Coincident with the stupor, the respiration assumed the Cheyne-Stokes' type. Pulse was rapid and there was moderate fever. Sensation was evidently better on the left side than on the right. Temperature sense was well preserved. Motion was better on the left side than on the right. Both eyes were occasionally opened in a sluggish way. There was no facial palsy and no spastic condition. During the five days intervening between the patient's admission to hospital and its death, the temperature rose at irregular intervals. The respiration continued to be of the Cheyne-Stokes' type and a progressively increasing spastic condition was noticed, involving both arms and legs. The stupor increased, but the child was kept alive for a while by tube feeding. Autopsy revealed no cause for the above symptoms and bacteriological tests were negative. The author alluded to previously reported cases presenting unusual nervous symptoms.

American Medicine, June 20, 1903.

Management of Malignant Disease of the Uterus.—Geo. Erety Shoemaker declares that the only hope of permanent cure of malignant disease of the uterus is in the early diagnosis at a time when only one of the classic symptoms may be present, or when no one of them has become marked. The keynote of the whole subject is investigation with the aid of the microscope. In cancer of the body nothing can be detected at first by the eye or hands, except possibly slight enlargement of the organ. The old idea that abnormal symptoms, such as excessive bleeding or discharge occurring in a woman after the age of thirty-five years, may be due to an approaching menopause, has long since been exploded, but it is still responsible for thousands of deaths. Much may be done toward the prevention of cancer by the repair of serious injuries to the uterine cervix and by the connection of its gland degenera-

tions. All cases are suitable for hysterectomy and complete removal of broad ligaments, tubes, and ovaries, as much cellular tissue as is possible about the uterine attachments, and a part of the upper vagina. When the disease is apparently confined to the parts mentioned. In the later stages of recurrent or inoperable growths, the use of the *x*-ray as a palliative in the pelvis appears to be considerably limited by the deep-seated location of the parts. In late cases with sloughing, strong solutions of potassium permanganate give great satisfaction in the hands of the patient for daily use. The cases should be investigated early in which any of the symptoms of cancer are shown. The method of operating must be determined by the case, but every patient should receive in some form thorough treatment by the actual cautery before any lymph spaces are opened by any other form of operation.

Chlorosis.—S. H. Rosenthal says that this disease is nearly always found in girls between puberty and the age of twenty-four years. Some writers claim to have seen it in men, but the reported cases are very few. Among the first subjective symptoms are malaise, headache, languor, vertigo, dyspnœa, and palpitation. There is perversion or loss of appetite. Borborygmus and tympanites are troublesome. These symptoms are often intense. In some cases gastric ulcer exists as a complication. The impoverishment of blood in chlorosis has reference chiefly to the red corpuscles and in less degree to the albuminous constituents of the plasma. There is a reduction in the quantity of hæmoglobin with or without diminution of the cells. This condition of disproportionate diminution of hæmoglobin, known as oligochromæmia, is the distinguishing feature of the disease over all other anæmias. At times there is quite a large reduction of the red cells. The hæmoglobin will be down to 30 or 40 per cent. The white cells are but little affected. There is a great variety in the course and prognosis of chlorosis. The disease never endangers life except by complications. The treatment is comparatively simple when complications do not exist. The tettering of hygienic surroundings in the early stages will often do much. Outdoor life, exercise in moderation, withdrawal from school, no working in shops, good nourishing food, and the internal administration of iron practically completes the treatment. The absolute rest cure is indicated when the disease is well advanced. Arsenic has been strongly recommended. All complications should be met symptomatically and promptly treated. It may, however, be months before final cure is established.

The Lancet, June 13, 1903.

Embolism in Acute Rheumatism.—The patient of A. Brownlie was a boy of eight years with his first attack of rheumatism, in the course of which endocarditis had developed. Suddenly he was seized with a hemiplegia of the right side with aphasia. The upper branches of the facial nerve were not involved, as the orbicularis palpebrarum and the frontalis muscles were intact, this fact pointing to a supranuclear lesion. It was also noted that the voluntary movements of the face were more impaired than the emotional. Electrical tests were not applicable. The hypoglossal nerve was also involved, the patient being unable to put out the tongue straight, but it deviated toward the paralyzed side. The arm was more completely paralyzed than the leg. The thoracic and abdominal muscles were not involved. Hemianæsthesia was present and was more marked in the arm. The deep reflexes were increased in the arm and leg, ankle clonus being well marked. The boy eventually died from asthenia and cardiac failure. No autopsy was obtainable, but the author has little hesitation in saying that there the case was one of embolism of the left middle cerebral artery with softening of the supplied areas of brain tissue, including the posterior part of the internal capsule.

Chronic Volvulus of the Sigmoid Flexure.—H. W. Allingham and E. C. Bridges report the case of a man aged thirty years, subject to attacks of constipation with great abdominal pain and ending in vomiting. As a rule flatus passed during the attacks and the bowels promptly responded to the usual cathartics. No blood or mucus was passed. Following one of these attacks, which did not yield to the usual measures, a distinct sausage-shaped swelling could be felt in the left iliac region. It was very painful to pressure. Symptoms of intestinal construction soon manifested themselves and it was decided to operate. The ordinary incision for left inguinal colotomy was made and a coil of bowel much distended with gas came into the wound. This was punctured and when drawn out was found to be a volvulus of the sigmoid flexure, to which was attached the mesocolon. Adhesions were very numerous. These were broken down and the volvulus reduced. Before the wound was sewed up, the sigmoid flexure was attached by two sutures to the abdominal wall to prevent a recurrence of the volvulus. With the exception of a slight thrombosis in the left leg, the patient made an uninterrupted recovery. Allingham is disposed to believe that the volvulus was always present and gave symptoms only distended with flatus. One year after the operation the patient was reported as being perfectly well. He had had no return of his old symptoms and his bowels acted freely without medicine.

Parasyphilis.—G. Ogilvie defines a parasyphilitic affection as one syphilitic in origin but not in nature. Its two characterisic features are the following: (1) It is met with, independently of syphilis, being due to other causes as well, while true syphlitic lesions, such as mucous patches and gummata, are never produced outside the domain of syphilis; (2) The iodides and mercurials have a totally different effect upon parasyphilitic affections from that which they are known to exercise on true syphilitic lesions. These drugs have on the former either no effect at all, or it is at the best slow and incomplete. Ogilvie reviews the statements made by Fournier and Hutchinson upon the subject. The general argument of his article is that the term parasyphilis is a sort of pathological lumber room—in other words, many lesions following syphilis are called parasyphilitic for want of a better understanding of their relations to the primary specific trouble. He is not disposed to give much credence to the theory of the effect of transmitted syphilis on the third generation. He says that the idea underlying the doctrine of parasyphilis is not new. Any specific disease may lead to sequelæ devoid of all specificity in the same way as war may lead to famine. Under different names, such as quaternary-syphilis, pseudo-syphilis, post-syphilis, etc., exactly the same idea has at different times made its appearance in the history of syphilography. What is particularly new in the modern teaching of parasyphilis is, apart from the name, the enormous extension given to the deleterious and deteriorating influence of syphilis upon the race.

The British Medical Journal, June 13, 1903.

Rapid Effusion of a Large Amount of Fluid into the Pleural Cavity.—W. Hale White reports the case of a woman, twenty-two years of age, who was admitted to Guy's Hospital suffering from tubal nephritis with mitral constriction and incompetence. On December 16, 1892, her right pleural cavity was aspirated, and, as far as could be ascertained, all the fluid which was 36 fl. oz., was removed. Thirty hours after, on December 17, 106 fl. oz. were aspirated; 78 hours after this, on December 20, 120 fl. oz. were aspirated; 30 hours after December 20, on December 22, 50 fl. oz. were aspirated; and on February 12, 1893, 30 fl. oz. were aspirated, making a total of 342 fl. oz. of clear serum removed from the right chest. It appears, therefore, that after the first aspiration, the fluid collected at the rate of 3½ fl. oz. an hour, and after the second and third at the rate of about 1½ fl. oz. an hour.

Morphine in Puerperal Eclampsia.—W. Boxer Mayne reports two cases. The first case was that of a young country woman, about five months pregnant, with a history of two previous miscarriages, who had suddenly fallen into a fit. About breakfast time she had lost her sight for a time, and had "fainted," falling on the grate, rather severely burning her face; during the day she had complained of great headache, and about 7 P.M. had developed the fit referred to, in which she was much convulsed, had gone black in the face, and had bitten her tongue. It being so early in pregnancy, the os being undilated, and not more than two fits having occurred, it was decided that the morphine treatment should have a trial, and accordingly Dr. Mayne gave a hypodermic injection of morphine sulphate gr. ¼, at the same time placing croton oil (℥ij) upon the tongue, and wrapping her in a big blanket wrung out of very hot water. The next day the patient was quite sensible, having had no more fits, and having had free action of the bowels and skin. The woman eventually miscarried some three weeks later, the fœtus having apparently been dead for some time. She progressed satisfactorily. The second case was that of a multipara, eight months pregnant, having had a family of thirteen, in addition to two miscarriages. She had had six fits during the early hours of April 18, the first at 4 A.M. Dr. Mayne was sent for at the onset of the sixth fit; by the time he reached the house the convulsion had passed off, leaving the patient semi-comatose. On the strength of the success in the case already alluded to he gave straightway a hypodermic injection of morphine sulphate (½ gr.), there being no signs of labor setting in. From the time of the injection no recurrence of fits took place. At the same time he had the woman given a hot pack, and had the bowels well cleared out. The same evening he gave another hypodermic injection of ⅓ gr.; by this time the woman clearly understood what was said to her. Urine had been passed during the convulsions, but none during the day. Next day, however, a little

was passed, which on examination contained half albumin. She then commenced to make daily the most satisfactory progress, the urine on the eighth day being free from albumin, and passed copiously.

Berliner klinische Wochenschrift, June 1, 1903.

Does the Glycogen Reaction of the Leucocytes Support Metchnikoff's Theory.—Siegfried Kaminer says that it does not, since it is present in leucocytoses which are not due to infection, but which are produced by other means, such as the inoculation of spermin, etc. Alfred Wolff, in his recent work, has commented upon the irregularity with which he was able to elicit the glycogen reaction in the various infections. This was without doubt due to the methods which he employed. He used Ehrlich's new method, while the extended experience of the author conclusively demonstrates that the reaction is much more regularly produced with Ehrlich's old method. This certainly accounts for the variance between the results of Wolff and those of the author.

Treatment of Chronic Catarrh of the Large Intestine.—J. Boas refers to v. Aldor's recent article in No. 19 of the *Berliner klinische Wochenschrift* (see MEDICAL RECORD, June 6, 1903), and says that it is not possible to accomplish the high enemas there recommended. It is impossible to introduce a tube into the colon from the rectum upward for 85 cm. Much experience, both upon cadavers and the living subject, has definitely settled this point. Furthermore, the histories of v. Aldor's cases are defective. Especially is the diet upon which the patients were placed not mentioned. Boas has for several years treated these cases with good results solely upon dietetic principles. It can at least be affirmed that the favorable results obtained by v. Aldor were not due to the so-called high enemas which he employed, because such are not possible, and that other factors were responsible therefore.

Löwit's Bodies in the Nuclei of Lymphocytes and in Myelæmia.—Paul Reckzeh reports the microscopical examination of the leucocytes according to Löwit's methods in cases of lymphatic leukæmia, pernicious anæmia, myelogenous leukæmia, chlorosis, diphtheria, typhoid fever, scarlet fever, eosinophilia from mercurial dermititis, secondary anæmia in advanced phthisis, and in healthy blood. The bodies as described by Löwit were found in all cases, although most abundantly in those of lymphatic leukæmia. This substantiates the views of Türck and Bloch, that they are not peculiar to the blood of leukæmia. Their significance is in doubt, but it is improbable that they are degenerative appearances as suggested by Bloch, since they are found in non-degenerating leucocytes in fair numbers. Five cases of myelogenous leukæmia were examined for the presence of Löwit's "Hæmamöba leukæmiæ magna." By following his methods these forms were demonstrated in all cases, but they were also abundantly in a case of mercurial dermitis. It is thus seen that these bodies also are not exclusively found in leukæmic blood.

Münchener medicinische Wochenschrift, June 2, 1903.

Necrosis of the Gall-bladder.—Czerny reports two cases and advises against extirpation of the gall-bladder, except in those cases in which the necrosis is extensive. The operation most frequently to be employed is that in which the gall-bladder is opened, evacuated, and thoroughly cleansed. The walls of the bladder are then united and the wound closed, except in those cases in which previous suppuration has taken place when drainage is used. Under the latter circumstances, the biliary fistulæ heal in about three weeks after the operation.

Acute Necrosis of the Mastoid and Temporal Bone Following Scarlet Fever.—G. Heermann reports three cases. The clinical history differs from ordinary mastoid disease in that the initial subjective symptoms are slight and liable to be passed over with but little attention. Herein lies the danger of the condition, for in due time the situation becomes serious, requiring extensive and frequently futile operation. The only safety lies in an early and complete removal of the necrotic bone. The bacteriological status of the necrosis is probably diversified, but in the cases here reported streptococci and staphylococci were found in all.

Fatal Injury from a Horse Kick.—Alfred Riedel reports a case which is of interest on account of the extensive lesions found post-mortem. The patient received a horse kick in the right side of the abdomen. He immediately became unconscious and soon died. Upon autopsy, the abdomen was externally contused. The liver was torn apart and its parenchyma crushed and more or less destroyed. The right kidney fell into two pieces when removed, its substance being greatly mangled. The peritoneal cavity contained an enormous amount of blood, as did also the urinary bladder. The three lower ribs on the right side were fractured, the tenth being broken in several places.

A Case of Synechia Pericardii Treated by Talma's Operation.—Paul Clemens reports a case of synechia pericardii which was of many years' standing, and for the ascites of which all the usual measures had been repeatedly tried in vain. It was finally decided to perform Talma's operation, in the hope that this symptom would be permanently relieved thereby. The result, however, was a failure in that the ascitic fluid began to accumulate in a few days following the operation and maintained fully as large proportions as previous thereto. The reason for the failure of the operation is not plain, but it is probable that the long previous duration of the case was responsible therefor.

French and Italian Journals.

Arsenic in a Hen's Egg.—M. Bertrand, having been led by his researches on the normal arsenic in the organism to believe that this metalloid is one of the constituents of active cells, made a study of hen's eggs from this point of view. His predictions were verified, for he found arsenic in appreciable amounts not only in the yelk, where it is relatively abundant, but also in the white in the shell and in the membranes.—*Revue Française de Médecine et de Chirurgie*, No. 28, 1903.

Puerperal Stomatitis.—Albert Jobin concludes that stomatitis, especially of an ulcerative nature, is one of the complications of the puerperal state. Its nature is that of an infection, and the best treatment consists in washing the mouth with antiseptics. Antiseptic mouth washing should be given as a prophylactic measure to all women after confinement, especially if they have dental or alveolar lesions, or if they suffer from renal insufficiency.—*Le Bulletin Médical de Quebec*, May, 1903.

The Etiology of Hydrophobia.—G. Daddi experimented upon dogs, and in every case in which rabies was proved to be present, he found the little bodies described by Negri. These bodies, so constantly found in the nerve centers of animals who die of hydrophobia, would appear to be parasites of some nature, rather than degenerative form of cells. Whether they are the causative element of hydrophobia or not, they appear to furnish a sure method of diagnosis of the disease.—*Rivista Critica di Clinica Medica*, May 30, 1903.

The Gastric Function in Animals Deprived of Their Spleen.—Torindo Silvestri says that the general conception in regard to the spleen is that its action is due to an internal secretion the functions of which are pepsinogenic and trypsinogenic, whence the disturbances of digestion which would follow its removal. From his experimentation, however, he claims to have demonstrated that there is no trypsinogenic secretion in the spleen, and that the action of the congested spleen upon a pancreas inactive toward albuminoids is only because of its containing blood and that in large amount, and more especially because of the infarcts of leucocytes. —*La Riforma Medica*, May, 27 1903.

Asthma from the Point of View of Life Insurance.—M. Mahillon concludes his review of the subject by the statement that applicants under forty years of age without tuberculous family history, who are not exposed to contagion, whose attacks occur at long intervals, and are of short duration, who do not expectorate, nor suffer from respiratory troubles, whose hearts are sound, in whom there is no arteriosclerosis, and who do not practise any profession liable to cause a return of the asthmatic attacks nor to lead to pulmonary affections, are admissable for a limited term or even for life. Asthmatics over forty-five years, obese, and open to the suspicion of a fatty heart, affected with arteriosclerosis, gouty or emphysematous, or subject to bronchial disorders, are inadmissible, or at least to be taken only as impaired risks.—*La Médicine Moderne*, June 3, 1903.

Conservative Surgery of the Uterine Appendages.—Hector Traub reaches the following conclusions: In the majority of cases of salpingo-ovaritis, medical treatment is all sufficient. Should medical treatment be insufficient or contraindicated, a radical operation should never be resorted to at once. The first step should be a posterior colpotomy. If by means of this posterior colpotomy the affection is found to be tuberculous, hysterectomy should be performed as soon as possible. In cases of hydrosalpinx rebellious to repeated colpotomies and needing further intervention, and in cases when sterility is to be overcome, conservative abdominal operations (resection, salpingotomy, salpingo-ovarosyndesis) are indicated. Salpingorrhaphy should be kept as an accessory operation during the course of a laparotomy for whatsoever indication performed.—*Annales de Gynécologie et d'Obstetrique*, May, 1903.

Gastroenterostomy.—M. Vallas states that the chief indication for this operation is stenosis of the pylorus. Unfortunately in the majority of cases the stenosis is due to a neoplasm, in which case we can hope for palliation only, not cure. The immediate results, however, are of the best, and patients have been known to live on for two years. If the stenosis be merely cicatricial, the operation is curative. Gastro-entero-anastomosis, is also indicated to give absolute rest to the stomach, as an ulceration of the stomach, when the accompanying pain is unbearable, or the hemorrhages becomes dangerous from their abundance or their frequency. The author is not aware of any contraindication to the operation. He has had twelve deaths out of sixty cases, which, however, were not carefully selected, as he took all cases brought to him whatever their condition—*Lyon Médical*, May 31, 1903.

Physiological and Therapeutic Properties of a Serum Extracted from Milk.—R. Blondel says that the serum of cow's milk obtained by rapid coagulation, at 100.4° F. by the aid of an acid, neutralized with soda, and filtered. is endowed with remarkable properties. In a healthy subject, a daily hypodermic injection of 20 c.c. increases the appetite and at the same time diminishes weight. Given the day after a gouty attack it determines a second attack with an enormous discharge of uric acid. It diminishes blood-pressure to an extraordinary degree, and in a more constant and durable manner than does Trunecek's serum. In infectious diseases it lowers the temperature very markedly. The author has used it chiefly in cases of puerperal and surgical infection, and is well pleased with the results obtained. There are no disagreeeable effects attending the injection, except possibly a sensation of cold in the part in which the injection was given, which comes on about four hours later, and is of very temporary durations. A slight cloud of albumin may form in the urine from the second day of the treatment, but it is not marked at any time, and disappears with the cessation of the injections.—*Revue de Thérapeutique*, June 1, 1903.

The Pathogenesis and Treatment of Puerperal Eclampsia.—E. Bonnaire says that a consideration of all the theories held in regard to this affection lead to the conclusion that it is simply the result of some form of toxæmia, the source of which may be the mother of the fœtus. Preventive treatment consists in an absolute milk diet. If an attack has occurred the chief effort should be to prevent another; the first indication is to rid the system of as much of the toxin as possible, for which purpose bleeding to the amount of 300 to 500 grams, replacing it later by its equivalent of physiological serum, is advisable. The latter should be injected subcutaneously, not endovenously. A drop of cotton oil in a tablespoonful of castor oil should then be given to clear the intestinal tract, or a saline purgative may be chosen instead. Diuresis must be secured. About four to six quarts of mixed vichy and sterilized water is to be administered daily, and adhered to until the patient shows signs of improvement; milk may then be added to the water, and finally pure milk be given. In halations of oxygen will aid in the combustion of the toxins. A second indication is to calm the nervous system, which may be accomplished by chloral. The author also describes the obstetrical treatment.—*Le Progrés Médical*, May 30, 1903.

Annals of Surgery, June, 1903.

Gunshot Wound of the Longitudinal Sinus.—The patient of B. Farquhar Curtis was a man of forty-two years. The person firing the shot stood some twenty feet behind and considerably below. Examination five hours later revealed a wound in the median line on the back of the head. The patient had considerable headache and dimness of vision, but was able to walk and had no motor or sensory paralysis. The skull was trephined, the area opened being nearly one and a half by two inches, and a wound was found in the longitudinal sinus near the torcular Herophili. Severe hemorrhage accompanied the removal of the bone fragments, and this, according to the author, teaches the most important lesson of the case. The technical deduction is obvious that the fragments over the sinuses should not be disturbed until the surgeon has removed sufficient of the surrounding bone to give him complete control of the bleeding point. The patient in the present instance finally recovered, though with some impairment of vision. During convalescence he had several periods in which he was quite irrational, but his final mental condition was good, though he remained nervous for a long time.

The Pathology of So-called Bone Aneurysms.—According to H. R. Gaylord there are on record but eight clinical records of cases of this nature. He reports one additional case. From his own experience and a review of that of others he believes that the greater portion, if not all, of the cases reported under this heading were originally medullary sarcoma, and he would further maintain that while these tumors may present the characteristics of aneurysm, their etiology and the mechanism of their development have little in common with that affection. Consequently it would be preferable to drop the term "bone-aneurysm," substituting therefor that of "pulsating sarcomatous hematura of bone." Some doubt is thrown on the accuracy of diagnosis in all of the former cases. In two of the original five, no microscopic examination was made. In the remaining three, it may have been that the tumor was originally of sarcomatous nature, and that the characteristic structure had disappeared. A factor which must be of importance in the development of these large cystic cavities is the frequency with which extensive hemorrhages occur in the substance of the tumor. The effect exerted upon the sarcomatous tissue by these extravasations of blood, especially when the whole tumor is encased in a shell of bone, must so interfere with the nutrition of the cells as not only to impede their growth, but in many cases to lead to their complete disintegration.

The Drowning of Patients in Fecal Vomit During Operations for Intestinal Obstruction and Septic Peritonitis.—E. Wyllis Andrews believes that the accident of drowning is an ever-present danger in septic laparotomies. Fluid rapidly accumulates in the bowel, and though the stomach may at first be empty sudden access thereto from the bowel may occur when the tone of the cardia and pylorus is relaxed by extreme depression. Consequently the stomach fills, and the throat reflexes being abolished by the anæsthetic, there is no spasmodic expulsion when the trachea and bronchi are flooded. His conclusions are as follows: (1) Flooding of the air passages by fecal vomit is a real danger, and probably has caused many unexplained deaths. (2) Resuscitation is impossible or very difficult. (3) The fluid may flow by gravity through the relaxed stomach sphincters directly out of the intestine where it has accumulated in enormous quantities. (4) The accident occurs with great suddenness and with a stomach supposedly empty. The suffocation may be so complete that no outcry is made and may not be noticed by the attendant. (5) It may occur as late as an hour after anæsthesia, or at any time until consciousness is restored. (6) We have no evidence that it can occur during consciousness even *in extremis*. (7) After septic laparotomy, patients, when returned to bed, should be watched without even momentary intervals to full consciousness. (8) The suggestion made that as many as possible of such cases be operated under cocaine anæsthesia is of the greatest importance

Myositis Ossificans.—W. J. Taylor reviews the literature of this affection and reports two cases, one traumatic and the other non-traumatic. The first case was that of a young man kicked by a horse in the anterior middle third of the thigh. It was at first thought that the limb was broken, but he was able to get up and walk. Soon the severe pain passed away and he was able to ride horseback though with some pain at the injured spot. When seen three weeks later there was a marked swelling over the site of injury. It did not feel bony, but gave the sensation of an organized hematoma beneath the periosteum. Incision over this area showed the whole area of the bone, especially of the anterior surface—enlarged and the periosteum thickened, and the muscles—particularly the deeper fibres—containing small bony particles. The pieces of bone and muscular tissue removed were directly in contact with the periosteum, which was elevated and the bone beneath found roughened. The bone was curetted, all the thickened muscular portions removed, and the wound closed. Recovery was uneventful. Microscopical examination of tissues removed strongly suggested the diagnosis of myositis ossificans.

Case 2 was that of a woman of forty years, who from her ninth year had a slightly tender lump over the left fibula near the junction of the middle and lower third. At fourteen, walking became distinctly painful, and the muscles gradually contracted until her foot was in marked extension, *i. e.* an acquired equinus. At sixteen, tenotomy was done, the deformity, however, returning immediately. Some *x*-ray pictures which she had had taken in Washington showed that there was apparently an irregular, sharp osteophyte growing from the fibula at the point indicated, and that the bone was thickened for some distance above and below this point. The muscles of the right calf were harder than those of the left. Operation was done in a manner similar to that of Case 1, the design being to remove the supposed osteophyte, lengthen the tendo Achillis and to remove all the supposed ossified plates. Microscopical examination of the tissues removed showed a condition of myositis fibrosa passing into myositis ossificans.

Book Reviews.

Why Soldiers Desert from the United States Army. By Ellwood Bergey. Philadelphia: Wm. F. Fell & Company, 1903.

The author of this book does not leave his readers long in ignorance of the point of view from which it is written, for in the preface we find the following statement: "So unjust is the treatment of our soldiers, so contrary to sense, honor, exigency, and reason, that a searching investigation into every department of the organization fails to reveal a single redeeming or commendable feature." This tone of sweeping condemnation pervades the entire volume. With regard to the extent of desertion from the United States Army, the assertion is made, based, it is said, on official records, that the percentage is greater than in the case of England, France, Germany, Italy, Spain, Greece, or Belgium, the loss to the country through desertion being estimated at $1,000,000 annually. Figures are quoted from the report of the Judge Advocate-General, for 1896, showing desertions from eight western army posts aggregating from 1.96 to 14.08 per cent., of the enlistment at those posts, respectively, the present author's explanation of the higher percentages being "improper food and brutality." Mr. Bergey submits these conclusions, reached, he says, "after an impartial and painstaking investigation into the United States Army, extending over a period of many years: "That at enlistment the American private soldier is the best in the world, mentally and physically; that in the following particulars, namely, the death rate from "disease" and "injury," the number of discharges in home territory, by reason of disability, the rate of desertion for the last thirty years, the number of suicides and cases of insanity resulting from bad treatment, the number of trials by courts-martial, the number of sentences to guard-houses and military prisons, the unlawful disposing of soldiers' rations, by officers, and the general treatment of the private soldier—our army compares *unfavorably* with the military establishment of any other civilized power. Charges are made that, for many years, including the present year, enlisted men have been tortured, and that, since the beginning of the Spanish-American War, innocent soldiers have been executed, by order of commissioned officers, while others are now undergoing imprisonment. The existing conditions are attributed in brief to polities and to making the private soldier dependent upon the mercy of his superior officers. The remedies suggested are: substantially higher pay for enlisted men, abundant rations properly prepared, sanitary quarters, food, and housing always to be exactly alike for officers and men, free speech for the latter, a two years' service limit, amnesty to deserters, abolition of salutes and other practices marking distinctions between officers and men, and the prohibition of torture and violence. Several particulars touched on in the volume under consideration may be noted briefly here. Attention is directed to the fact that in the period of peace from 1880 to 1890, both inclusive, the death rate in the United States Army ranged from 6.33 (1889) to 11.60 (1883) per 1,000, while the average death rate of the British Army among troops at home, for a similar period, 1889 to 1899, both inclusive, was only 4.32 per 1,000, and that of the Canadian Army, for ten years, was only 3.5 per 1,000. The dates for the last-named army are not given, nor is there any explanation as to why the same years are not selected for comparison in the case of our army and that of Great Britain.

A number of incidents illustrative of gross negligence or brutality, or both, in the treatment of enlisted men in our army are brought forward, some in connection with the Spanish-American War, including the well-known case of Private Riehter. A letter purporting to have been written from Bilibid Military Prison, Philippine Islands, by Lawrenee F. Hoon, Company K, Fourth United States Volunteer Infantry, to his father, is quoted *in extenso*. If the facts are substantially as represented, they certainly show a gross abuse of power on the part of the court-martial and of the reviewing authorities. From the prisoner's statements, it appears that, an order having come for the promotion of one man from each regiment, he applied by letter to General Otis for promotion, whereupon he was arrested, charged with addressing a superior officer without the consent of intermediate officers. He did not know the offence was a crime, but was nevertheless sentenced by a court-martial of six officers to be dishonorably discharged and confined for one year in Bilibid Military Prison. Five months' pay, amounting to $78, was confiscated. The marked inefficiency and failure of the War Department under Secretary Alger come in for a share of the author's denunciation. It may be noted also that he expresses himself as opposed to the canteen system.

The Surgical Diseases of the Genito-urinary Organs. By E. L. Keyes, A.M., M.D., LL.D., Consulting Surgeon to the Bellevue and the Skin and Cancer Hospitals; Surgeon to St. Elizabeth Hospital, etc.; and E. L. Keyes, Jr., A.B., M.D., Ph.D., Lecturer on Genito-urinary Surgery, New York Polyclinic Medical School and Hospital; Surgeon to the Out-patient Department, St. Vincent's Hospital, etc. A Revision of Van Beuren's and Keyes' Textbook. With one hundred and seventy-four illustrations in the text and ten plates, eight of which are colored. New York and London: D. Appleton & Co., 1903.

Tempora mutantur, et nos mutamur in illis! Some of us can remember back to the days when it was Van Beuren and Keyes, and then when it was Keyes alone, and now it is Keyes and Keyes. Fortunately, there is no evidence of deterioration by age, and this revision of the original does full credit to the late senior collaborator. There are many new methods of treatment little dreamed of in the days of the original, which are here fully described and well illustrated. The publisher's part has been done in exeellent taste. The student will find in this work a textbook in which he can have full confidence as a guide and aid, and this applies equally to the man in practice.

Diseases of the Skin; Their Description, Pathology, Diagnosis, and Treatment, with Special Reference to the Skin Eruptions of Children and an Analysis of Fifteen Thousand Cases of Skin Disease. By H. Radcliffe Crocker, M.D. (Lond.), F.R.C.P. Physician for Diseases of the Skin in the University College Hospital; Honorary Member of the American Dermatologieal Society, etc. Third Edition, Revised and Enlarged, with four plates and one hundred and twelve illustrations. Philadelphia: P. Blakiston's Son & Co., 1903.

When one reads on the title-page that this edition has been enlarged, he can well believe the statement. There are no less than 1,466 pages, exclusive of a batch of advertising matter, that the publisher has thought well to inflict upon the purchaser. The work is unwieldy and altogether too discouraging to the novitiate in skin diseases. Aside from this the author presents, perhaps, the best and most complete treatise extant in the English tongue.

The second edition has been out of print for three years. This is sufficient evidence (aside from the mass of new material) that the present edition has not been brought out in a hurried manner for trade purposes. There is evidence throughout of thoroughness and a desire to include all advances up to printing time. Among the new material we find something about radiotherapy and radiodermatitis, various new forms of erythema, acrodermatitis, toxic serum eruptions, porokeratosis, blastomycosis, and, indeed, a long list of those things that dermatologists feel called upon to keep discovering and then naming. The author is entitled to sincere congratulation, and ours is hereby tendered.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc., assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-patient Department of the Jefferson Medical College Hospital. Vol. I, March, 1903. Surgery of the Head, Neck and Chest, Infectious Diseases, Including Acute Rheumatism, Croupous Pneumonia, and Influenza, Diseases of Children, Pathology, Laryngology and Rhinology, Otology. Philadelphia and New York: Lea Bros. & Co., 1903.

The regularity with which these quarterlies come to hand laden with new matter indicated that in the flight of months vast work is being accomplished throughout the world in advancing medical science. Sometimes it makes one feel as though there were too much, and a desire arises to have the whole bulk of reports still more concentrated so that out of the mass that is *new* we could have the really little that is essentially and everlastingly and practically *true*. However, this, like much other modern literature, has its place of usefulness, and here Frazier Herrick, Crandall, Hektoen, Turner, and Randolph have done faithful and good work in gathering the material for their various departments. The usual standard is maintained.

SECOND DAY—WEDNESDAY, MAY 13.

Gastroenteric Infections of New-born Children.—Dr. Irving M. Snow of Buffalo read this paper. He said that the period most dangerous to human life was the first four weeks of an individual's existence. A few years ago congenital debility was a term used to explain 80 per cent. of early deaths. Atelectasis, intracranial hemorrhage and sepsis were not given proper recognition as etiological factors in infantile deaths. As an avenue of infection in new-born children the alimentary tract was an important consideration—a fact that had been overlooked in many textbooks. The introduction of the infection might be accomplished in various ways. The accoucheur, the nurse, the mother's breast, the milk, and not so very infrequently the amniotic fluid might be responsible for the infection. The infection in a young child soon became general, no matter what the path of entrance might have been. Dyspepsia might be responsible for vomiting, diarrhœa, colic, and other signs, but a severe gastroenteritis always meant an infection. The dividing line between dyspepsia and gastroenteric sepsis as manifested by the physical signs varied with the virulence of the infection. Five cases were described by Dr. Snow which had severe gastroenteric infections. Fever, rapid pulse, irregular respirations, vomiting, diarrhœa, and extreme prostration characterized the attacks. Blood and mucus were present in the stools, which were very offensive; in some of the cases tonic muscular spasm was observed. Rigorous asepsis and careful attention to the toilet of the mouth were the essentials of proper prophylactic treatment. Sudden attacks of alarming seriousness in these cases were common; the children should therefore be closely watched. The most valuable therapeutic agents were strychnine, atropine, and artificial serum.

The Relation of the Bacillus of Shiga to the Summer Diarrhœas.—Dr. Simon Flexner of Philadelphia had been invited by the society to speak on this subject. He said that there had been considerable research and much study in the attempt to discover the cause of diarrhœal diseases, but that prior to recent investigations little definite information had been obtained concerning the cause of infantile diarrhœas. While conducting some investigations in the Philippines in search of a cause of dysentery, Dr. Flexner had no difficulty in establishing the existence of a well-defined microorganism which differed from the ordinary intestinal bacteria and which closely resembled the bacillus described by Shiga of Japan. It had occurred to Shiga that if certain bacteria were constantly present in these cases of dysentery it was probable that blood changes would take place which would make it possible to select, by means of the agglutination test, the bacteria sought for. The test was applied and an organism was found which gave the positive Widal's reaction. The bacillus closely resembled the typhoid organism, but a ready differentiation was rendered possible by certain definite characteristics. Since first described by Shiga, this bacillus had come to be recognized as an important etiological factor, if not the causes of a certain definite group of acute cases of dysentery in adults. Dr. Flexner thought that results of value might be obtained if the same method of study was applied to the diarrhœas of infants. At the Wilson Sanitarium near Baltimore fifty-two cases of summer diarrhœas of a severe type were studied under his direction. In forty-five of these the bacillus of Shiga was found to be present. The blood serum of these children not only gave a positive reaction with cultures obtained from their own dejecta and with organisms obtained from other children, but also gave a positive agglutination test with cultures obtained from Japan and the Philippines. In most of these cases in which the bacillus of Shiga was found blood and mucus were present in the stools. It was a very difficult matter to find the bacilli in formed fæces. When mucus was present it was less difficult, but the organisms were most readily obtained when both blood and mucus were present in the stools. In calling attention to a few points of practical importance, Dr. Flexner said that it was desirable for those who made an attempt to obtain the bacteria from the dejecta of diarrhœal cases, to first study the bacillus of Shiga, since the ordinary cultures closely resembled the typhoid and colon bacilli. He also called attention to a trick in the technique of colony transplantation. Experience had shown that the colon bacilli outstripped the bacilli of dysentery in growth, so that one could be reasonably sure that at the end of the first twenty-four hours most of the colonies were colon bacilli. It was suggested that all colonies which develop in the first twenty-four hours of incubation be marked with a blue pencil The cultures should then be allowed to grow for a second twenty-four hours; from the colonies which appeared in the second twenty-four hours cultures should be taken. In these the dysentery bacteria were most likely to be found. The culture medium which Dr. Flexner employed was glucose-agar. This medium was chosen because it was found that colon bacilli decomposed the glucose with the formation of gas, while the dysentery bacilli did not, a fact which allowed of a second means of colony differentiation. As the study of the bacteria of dysentery proceeded it was discovered that they were not of a single type. A group was recognized which corresponded to the original type described by Shiga. This group possessed marked agglutinating properties, but when cultivated on a manite medium did not change litmus. In addition to this group a second was recognized by Dr. Flexner which possessed all the cultural properties of the first, but differed in the character and degree of its agglutinating properties, and which turned litmus red when grown on a manite culture medium. That one type or the other was the cause of the dysentery was impossible to say at the present time; in some epidemics one type had been found, in others, another type; in still others both types had been present in the same case. In all cultures obtained from the children studied at the Wilson Sanitarium, that type of bacteria was found which produced an acid reaction when grown on a manite medium, and they were not the original bacilli described by Shiga. The future alone could determine the position which these organisms should occupy as etiological factors in diarrhœas.

In discussion, Dr. W. H. Park of New York said that there were many difficulties in the application of the agglutination tests. In his experience he had found the bacillus of Shiga to be present only when the stools contained both blood and mucus.

Dr. Henry Koplik said that he considered summer diarrhœa to be a very complex entity. The majority of cases occurred in artificially fed infants, and might be separated into several distinct groups. One class of cases was due to anatomical or physiological insufficiency of the gut, or the diarrhœa might be dyspeptic and dealt with as a foreign element. A second group of cases were caused by microorganisms contained in the food itself, the third group would include infectious cases, in which microorganisms had been introduced from the outside. A fourth group would include those cases in which amœbæ of one or another variety were present in the intestines. In summer diarrhœa it was probable that the action of many varieties of bacteria was combined in the formation of an exceedingly complex etiological factor. Dr. Koplik thought that the number of cases caused by the presence of the bacillus of Shiga was limited, and said that bacteriological research and clinical experience should go hand in hand in the further study of this important subject.

Dr. L. Emmett Holt of New York said that the work of Dr. Flexner had shown what might be looked for in a

certain type of cases. It was essential that evidence be obtained of bacterial invasion of the intestines by blood examination before it would be possible to say that a certain organism was the cause of the diarrhœa, even though the organism were constantly present in the stools. Dr. Holt had superintended a series of investigations of one hundred and twenty cases of diarrhœa. In thirty-seven of these the bacillus of Shiga was present, and in each case a marked blood reaction was obtained. In all cases in which blood and mucus were present in the stools, the bacillus of Shiga was found. In many cases, however, in which the stools contained an abundance of mucus, it was impossible to prove the presence of the organism. It was considered of importance to know how long after the subsidence of the acute symptoms the bacilli could be found in the stools, since in one case the bacteria were present six weeks after all acute symptoms had subsided. In the majority of cases the organisms were present, and the blood reaction obtained two weeks after the subsidence of acute symptoms. A careful study of many cases had revealed no characteristic pathological lesion. Dr. Holt had used, as a therapeutic measure, in several cases, some anti-bacteriolytic serum, which he had obtained from Dr. Flexner. In several cases an injection of this serum was followed by good results, the effect, however, was very transient, it being necessary to repeat the dose (10 c.c.) every day, or at most every second day. The serum treatment looked hopeful, but it must be given on the clinical diagnosis, since it required forty-eight hours to make a bacteriological examination.

Dr. Knox, who was in charge of the Wilson Sanitarium, said that blood was at no time excessive in the stools of the acute cases in which the bacillus of Shiga was found. In some few cases the organism was found in the mucus of the stools when no blood had been present. He added that he agreed with Dr. Holt in that there was no definite pathological lesion, or clinical feature which would serve to differentiate the cases in which the bacillus of Shiga was present from those classed as ordinary summer diarrhœas.

In closing the discussion, Dr. Flexner said that the problem was very complex, and that he had committed himself to no idea other than that the bacillus of Shiga occurred in some of the diarrhœas. Up to the present time the serumtherapy was entirely experimental and attempted to deal with an organism which held its poison closely bound up in its own protoplasm, differing in this respect from the diphtheritic bacteria, which set free a toxic element in the blood stream. The serum used in the diarrhœal cases was not to be considered then, strictly speaking, an antitoxin, but rather an anti-bacteriolytic serum. Any good results must come from its early use.

The Infections of the New-born.—Dr. S. McC. Hamill of Philadelphia presented this paper. He said that it was not his purpose to suggest a new classification of infantile infections, but in many respects the present classification was unscientific and should be revised on a strictly bacteriological basis. Six cases were reported which had been studied with Dr. W. R. Nicholson of Philadelphia—an extensive bacterial invasion had been the cause of death in each instance. A bacteriological examination of various organs had revealed the presence of streptococci, staphylococci, and colon bacilli; the germs having gained an entrance into the body of the child probably, for the most part, by means of the alimentary and respiratory tracts. These same varieties of bacteria had been found in the dust of the rooms in which the infants were kept, in the bedding, in various toilet articles, in the clothes of the mothers and other attendants. Cultures were also obtained from the bottle nipples and mothers' breasts and from the bath water of the infants. Careless and poorly trained nurses were probably responsible for most of these infections. Dr. Hamill said that preventive treatment was of great importance. The general aseptic technique of the maternity hospital staff should be insisted upon—no person aside from regular attendants should be admitted to the wards, and these should wear gowns and wash their hands before and after handling the infants. The children should not be kept in the same ward with their mothers but should be under the care of a careful and well-trained nurse. The breasts of the mothers should be carefully watched and kept clean, and the mouths of the infants should also be kept clean.

In discussion, Dr. Koplik said that he did not consider it necessary or wise to attempt to cleanse the mouths of the infants after they had once been cleaned at birth. An epidemic of sore mouths was cited which occurred at the New York Maternity Hospital, B. I., when the nurses were instructed to stop all attempts at mouth cleansing, The ulcers in the mouths of the babies quickly disappeared. The importance of keeping the mothers' breasts and nipples clean was emphasized.

The Etiology of Rachitis.—Dr. Roland G. Freeman of New York read this paper. He said that although this disease had been recognized for over two hundred and fifty years, it must be confessed that even to-day the exact cause was still unknown. The affection was a general disease and not merely an involvement of the long bones; cases occurred in temperate and cold climates; the individuals who suffered most were those who had come from a hot to a cold climate, most cases being found among the Italians and negroes. Race and climate were predisposing causes, the exciting cause seemed to be associated with the diet. One of the most recent theories was that rachitis was due to a lack of fats in the food.

Dr. Herter of New York, in a series of experiments on pigs and guinea-pigs, proved that fat starvation did not cause rickets, but did bring about a condition of mucoid degeneration, except in those cases in which there was an excess of carbohydrates in the food. The fact that artificial baby foods contained an excess of carbohydrates probably saved many infants from mucoid degeneration. Dr. Freeman had studied many cases of rachitis in New York, and had been led to consider that the persistent use of some unsuitable food was the most potent cause of rickets. The disease was especially common in children who had recently migrated from a warm climate.

In discussion, Dr. S. S. Adams of Washington said that rachitis was far less frequent since the knowledge of proper methods of modifying milk had become more complete and widespread.

Dr. Miller of Philadelphia emphasized the fact that want of sunshine and good air were very important etiological factors in rickets.

Dr. Cotton of Chicago said that it was very rare to find rickets in an infant at the breast. Such an occurrence almost invariably meant that the mother was giving abnormal milk. The improved methods of the modification of cow's milk had been of great value, but there was not sufficient attention given to the errors of lactation. It had become a habit with most physicians to shy at this point. More of an effort should be made to make the mother give good milk, and treatment if necessary should be instituted before the birth of the child.

THIRD DAY—THURSDAY, MAY 14

Some Chemical Analyses of Milk Mixtures.—Dr. D. L. Edsall of Philadelphia gave a brief review of a series of experiments which he had undertaken with the assistance of Dr. Charles A. Fife of Philadelphia. He said that it was a striking fact that no control had been furnished in milk modification, in view of the fact that accuracy, in modification was of such importance.

Dr. Edsall had found it of interest to make a series of analyses of modified milks, which he had obtained under varied circumstances, and to compare his results with those obtained by the original modifier.

A certain amount of the milk which he used had been ob-

tained from known and reliable sources and modified by known and reliable persons. Another portion of the milk had been obtained from unknown and unreliable sources and had been modified by unknown and unreliable persons.

In the milk that had been modified at a well-equipped laboratory by an efficient person, the fats came very close to the formula, few errors of more than .2 per cent. being found.

In many of the milk mixtures modified at home by trained nurses the error in the fat percentage was as high as 2 per cent. The proteids in all cases followed the formulæ more closely than the fats. In considering the question of milk modification, it must be remembered that an absolutely accurate percentage estimation was quite impossible, because the proteids in the best of milk, supposed to be of constant quality, might vary from ½ to 1 per cent. from day to day, while the fats might vary still more. In drawing some conclusions from the results of his analyses, Dr. Edsall said that the laboratory milks which he examined were practically free from criticism. The examination of specimens modified at home indicated that certain definite plans should be followed. The milk and cream should be obtained from a known and reliable source, and reliable and competent persons alone should be allowed to make up the milk mixtures.

The Determination of Fat and Total Solids in Milk.—Dr. Henry L. K. Shaw of Albany presented this paper. He said that he had found it of interest to make an analysis of thirty specimens of milk to determine the fats and total solids, using several tests for each sample and comparing the results obtained by the different methods. He found that Babcock's test, Gerber's test, and Holt's cream gauge gave the most constant results. Dr. Shaw exhibited a modification of Babcock's centrifugal apparatus, which he recommended for office use in the determination of milk fats. The total solids could be best determined by taking the corrected specific gravity and considering the percentage of fat; by using Richman's sliding scale the results could be readily obtained without the necessity of employing mathematics.

In discussion, Dr. S. S. Adams said that he had had several analyses made by expert chemists of modified milks, and that the utter unreliability of most of the milk specimens was appalling. He thought that most laboratory inaccuracies were due to carelessness and inefficient workers. The conical dipper, in his experience, had proved the most reliable domestic method of milk modification.

Dr. Cotton said that it was very important that the physicians should know the quality of the milk a mother was giving. Several examinations were necessary before any deductions could be made.

Dr. Chapin of New York said that the Babcock test had proved to be of great value in the estimation of fats. He thought that investigators were giving too much attention to the fats of milk, and too little attention to the proteids.

Dr. Edsall said that centrifugal machines were valuable aids in the determination of fats and sufficiently accurate for general clinical purposes. He added that it should become the habit of physicians to make examinations of milk as much of a routine practice as the examination of urine.

A Note on Abdominal Auscultation in Infancy.—In presenting a second paper Dr. Shaw said that he considered this means of diagnosis of great value, but that he had never seen mention made of it in textbooks. The respiratory sounds in infants and young children were transmitted to the abdomen, and could easily be distinguished from the intestinal sounds. A case of lobar pneumonia was described in which râles were heard over the abdomen before any signs of the disease could be detected over the chest. The râles, associated with acute bronchitis, had also been readily heard over the abdomen. The sounds were much clearer when abdominal distension was present.

A Report of Eight Cases of Pneumonia in Infants Treated with Antipneumococcic Serum.—Dr. Lovett Morse of Boston read this report and said that he had made many attempts during the last twelve years to obtain a serum which would prove of value in pneumonia in man, but results had been very unsatisfactory. He described eight cases which had been treated with antipneumococcic serum, which had been given in doses of 5 c.c. to 10 c.c. every four hours. From results obtained from these eight cases the following conclusions were drawn: in no case was their any effect on the temperature; in no case was the course of the disease shortened; in no case was the crisis postponed; in no case was there any effect on the pulse rate; in no case was there anything noticed to justify the assertion that there was any alleviation of the subjective symptoms:

In discussion, Dr. Jennings described a case of pneumococcimeningitis in which he had used antipneumococcic serum. Apparently the clinical phenomena of the disease were in no way influenced by the administration of the serum, nor were subsequent cultures of pneumococci inhibited.

A Case of Myxœdema.—Dr. George W. Acker of Washington, D. C., reported the case of a child which had had a perfectly normal and uneventful existence up to the eighteenth month, at which time it developed a severe attack of diphtheria, from which a complete recovery was never made. Six months later its general appearance began to change, it was unable to walk, the bridge of the nose became flattened, the legs became flabby and swollen, the abdomen became pendulous, the face puffy and devoid of all expression. The child took no notice of things and did not even know its own mother, it slept well, had a good appetite, it increased in weight but not in length. The anterior fontanelle remained open, the hair became straight, coarse, and dry, the thyroid gland was not palpable. The child kept its mouth open, its tongue was of large size and flabby, most of its teeth became decayed, Harrison's groove was marked. Thyroid extract was given in half-grain doses three times a day, the dose was gradually increased up to three grains three times a day. On several occasions the child had a sharp rise in temperature, the drug was promptly discontinued until the temperature fell to normal. A marked improvement followed the administration of the thyroid extract.

In discussion, Dr. Koplik described the case of a child nineteen months old which presented a typical picture of myxœdema. Thyroid extract was given until it was seven years old, when the treatment was discontinued. In less than a month the symptoms returned in a most aggravated form. Treatment was immediately resumed and improvement followed. This case was described to illustrate the necessity of keeping a case of myxœdema under constant treatment. A child was able to stand large doses of thyroid extract providing that the drug was pure—as much as nine grains three times a day had been given. A rise in temperature might be caused by an impure drug and should not be considered an indication for discontinuing treatment.

Dr. Cotton had had considerable experience in the use of thyroid extract, and thought that it rendered children more susceptible to the ordinary infections.

Pulmonary Osteoarthropathy in a Child Three Years Old.—Dr. T. M. Rotch of Boston read this paper, describing a case which he had seen with Dr. Hunter Dunn of Boston. A boy three years old had had an uneventful history up to the time he was two years old, when he developed measles, and later had whooping-cough. He apparently recovered from these attacks, gave no general symptoms, nothing especially wrong had been noticed with his pulmonary apparatus. Som

time later he developed a troublesome cough, which lasted a year, growing gradually worse, until relief was finally sought at the hospital. The child had never had night sweats or been troubled with digestive disturbances. Nine months before he was admitted to the hospital his finger-tips had begun to enlarge. A physical examination showed flatness on percussion over the left upper chest in front and dulness behind; on auscultation bronchial voice and breath sounds were heard over this same area, together with loud crackling râles. The child apparently felt well, it ran around and played, presenting no subjective symptoms of disease. The abdomen of the child was large, blood and urine examinations were negative. An examination of the sputum showed it to be loaded with Pfeifer's bacilli of influenza. An injection of tuberculin was negative in its results. The physical signs were interpreted to mean a consolidation in the left lung, that was possibly due to an unresolved influenza pneumonia.

In discussion, Dr. West of Ohio reported the case of a child three years old that had been a weakling from birth. When eight months old it began to cough. After an attack of measles the cough became worse, slight clubbing of the fingers was noticed. The chest was narrow and bowed backward. Anteriorly and posteriorly, coarse râles could be heard. On the finger tips the skin was rough, a condition which the family attributed to nail-biting. As the child grew older, the clubbing of the fingers became more marked. The treatment consisted of the use of creosote given by mouth and inunctions, under which the child improved.

A Case of Chondrodystrophy Fœtalis in a Child Fourteen Months Old.—Dr. J. Park West of Ohio presented this case, describing a child with a negative family history which had had a normal birth. Soon after birth, however, it began to develop a large round head, short thick hands and fingers; when five months old an angular curvature of the lumbar spine was noticed, there was occasional sweating about the head, the anterior fontanelle and frontal suture remained open, light exophthalmos was present. The child's skin was very loose, so that it appeared to have about two and a half times as much skin as was necessary, the muscles were soft, there was no joint involvement nor curving of the long bones. A noteworthy feature was a deviation of two fingers to the radial and two to the ulnar side of each hand. The child had been subjected to various courses of treatment, none of which seemed to alter its condition. It remained weak and made no attempt to sit alone. The chief difference in its appearance from a normal child was in the length and size of the bones. The shape of the head and the sweating were the only features which resembled rachitis.

Congenital Gastric Spasm of the Pylorus, with Specimen.—Dr. West reported this case of a child which he saw when it was twenty-two days old; it had had difficulty in retaining food since its birth, a condition which became more marked as the child grew older, until it vomited everything that had been taken into its stomach, at the same time giving evidence of severe pain. On examination, a swelling in the region of the pylorus could be felt which led to the diagnosis of hypertrophic stenosis. At the autopsy, an hypertrophic condition was found only of the circular muscle fibers which surrounded the pylorus. No relief was obtained in this condition from the use of drugs. Prompt surgical treatment was recommended for such conditions.

Prophylaxis in the Prevention of the Spread of Vulvovaginitis in Hospital Service.—Dr. Henry Koplik of of New York presented this communication and said there was no more annoying infection in hospital practice than vulvovaginitis. Aside from its repugnant features, it was a menace to the individual and a source of infection to others. All paths of infection had not been recognized, but there was always a definite source. It had been supposed, in general, that the infection was ordinarily carried by means of catheters, fingers, napkins, etc., but it had been definitely proved that a pure culture of gonococci when rubbed on the genitals of the female children did not always produce vulvovaginitis.

In children a urethritis or a proctitis was prone to give rise to a vulvovaginitis. A scant watery discharge was more to be feared, for it was apt to be neglected or overlooked. Any purulent rectal discharge should invariably be examined for gonococci. Among the many avenues of infection were mentioned bed-pans, catheters, nurses' hands and clothing, bed linen, rubber sheets, wash rags, and bath-tubs. When an enfected case was met with prompt and complete isolation should be practised, and every case, on admission to the hospital, should receive careful examination. Every female child in Dr. Koplik's hospital service had its own wash basin and toilet articles; each bed had a thermometer case attached to it, and if a child had any discharge the thermometer used for such a case was used for no other child but was kept in the case attached to that particular child's bed. A bed-pan once used on an infected patient was never again used on a clean one. As a precaution against infection from the hospital linen, every female child was protected by a vulvar pad, All bedding from an infected patient was sent to the hospital sterilizer before it was sent to the laundry, and was at times kept carefully apart from the other bedding. An additional precaution was taken in the wards of marking the bed of every infected case with a red bandage; no nurse attending an infected patient was allowed to touch a clean one.

In discussion, Dr. Chapin said that he had proved cases to be infected by taking cultures in which there had been no sign to arouse suspicion.

Dr. Dodson of Chicago said that the importance of this infection was by no means fully appreciated. It was unfortunate that the patients should be at the mercy of the nurse; he thought that it was very desirable to have nurses trained in practical bacteriology. Another fact of importance that was overlooked was that the sterilizing of infected utensils was frequently left to irresponsible persons. The ordinary injections as therapeutic measures were quite inefficient. Remedies should be kept in close contact with the parts almost continually.

Dr. Downing of New York said that the possibility of a foreign body should not be overlooked in cases of vaginal discharge.

Nasal Intubation for Relief of Dyspnœa Due to Acute Nasopharyngeal Swelling in Infants.—Dr. Wm. P. Northrup of New York described a case of acute swelling of the tonsils and pharynx in an infant, causing extreme dyspnœa and cyanosis. Syringing was not at all efficient, steam inhalations gave but little relief, tracheotomy was about to be resorted to as a last hope when it occurred to Dr. Northrup to introduce bits of soft rubber drainage tubes into the nares. After the tubes had been introduced about two inches the child showed immediate signs of relief and sank into a quiet sleep, the tubes being allowed to remain twenty-four hours. When the tubes were removed the child immediately became cyanosed and all the previous symptoms of distress were repeated. The tubes were promptly reinserted and, in Dr. Northrup's opinion, tided the child over a condition which would otherwise have proved fatal.

In discussion, Dr. Morse of Boston reported a case of acute nasal and pharyngeal obstruction, in which he had obtained prompt temporary relief by the use of adrenalin chloride.

O'Dwyer Intubation Instruments.—Dr. Northrup exhibited the most recent O'Dwyer intubation sets. The set contained two new small tubes for infants under one year of age, and a fixed obturator, so devised that it could not turn on itself.

Concerning the Nature of Still's Type of Chronic Deforming Polyarthritis.—Dr. D. L. Edsall of Philadelphia

referred to a type of chronic polyarthritis which Still had described, a condition which was readily distinguished from arthritis deformans. The disease, as a rule, appeared before the first dentition; it was accompanied with fever and associated with a general enlargement of the glands, but had no tendency to go on to bony deformity. Dr. Edsall described the case of a boy who was supposed to have been suffering from acute articular rheumatism. The child died when eighteen months old, at which time there was a general involvement of the joints, in all of which movement was greatly restricted. There was also a tendency to a general enlargement of the glands. An injection of tuberculin gave a marked reaction, which was both general and local in the joints, and lasted about twelve hours. Unless the joints were considered tuberculous there were no other signs of tuberculosis. Microscopic section, however, of the glands showed the presence of tuberle bacilli in small numbers, some of which were injected into guinea-pigs, but in no case did tuberculosis develop in these animals, a fact probably due to the low virulence and small numbers of the bacteria. From a study of this case, Dr. Edsall thought that the disease was probably dependent upon a tuberculous process.

Disturbances of Respiration in the New-born.—Dr. W. Reynolds Wilson of Philadelphia said that the respiratory disturbances of the new-born were included, for the most part, in the following conditions: asphyxia, congenital atelectasis, dyspnœa, and rapid respiration. The main causes of asphyxia were deficient abdominal muscular action, traumatic causes and paralysis of the respiratory center due to toxic influences arising from the alimentary tract. Dr. Wilson describes a case in which he considered the respiratory disturbances to be due to this latter cause. The signs of this condition might resemble Holt's fever of inanition. The principle causes of dyspnœa were congenital malformations, cardiac disturbances, pneumonia, stenotic dyspnœa, pressure dyspnœa due to an enlarged thymus, pulmonary apoplexy, dyspeptic dyspnœa, toxic in origin and diaphragmatic hernia, a condition which sometimes gave rise to periods of distressing dyspnœa. The chief causes of rapid respiration were dyspeptic, the ordinary pulmonary and systemic infections.

In discussion, Dr. Saunders of St. Louis said that apnea was sometimes caused in young children by the presence of the products of combustion thrown out into a room by gas logs. In cases of apnea, flagellation had proved a quick and efficient remedy, a good method being to snap the feet of the child with a rubber band. When a child had aspirated fluid into its lungs, great relief might sometimes be obtained by turning the baby upside down, and making it gag by tickling the back of the pharynx.

Principles of Infant Feeding as Based on the Evolution of Mammals.—Dr. Henry D. Chapin of New York read this paper. He said that the essential difference between the milk of various mammals was in the proteids which were nearly the same composition, but assumed different forms. In reviewing some facts relating to the development and nourishment of the young in the early types of mammals, Dr. Chapin said that the earliest types deposited eggs in a nest and nourished the young by the injections of milk into the mouth of the offspring, no teat being present. In a higher form the egg was deposited in a pouch in which the young animal was developed. The mother nourished the young by ejecting milk along the course of certain hairs. In still higher types the egg became hatched within the mother, and after birth the young animal became attached to the mammary gland of the mother, growing on the teat, but the young animal had no power to suck. Ascending again to the evolutionary scale, a type is found in which the young becomes attached to the uterine wall, and has a placental development. The development of an animal seemed to depend upon the ability of the mother for defence. About the third month colostrum appeared in the mother, a time which corresponded to the attachment of marsupials to the teat. From an evolutionary standpoint, it seemed logical to consider an infant as having three stages of development, a pre-placental of three months, a placental of six months, and a mammary stage lasting ten or twelve months. A child that has been early deprived of the breast should be considered premature. It was important that the changes which milk underwent in the process of digestion in a baby be studied, and it should be remembered that it possessed functions other than nutritive. In concluding, Dr Chapin called attention to the following considerations: (1) In development an infant passes through three stages, and should be looked upon as attached to the mother in all three. (2) At the beginning of the mammary stage an infant has only a rudimentary stomach. (3) During mammary development, the mother first changed the character of the infant's nourishment from colostrum to milk, and the infant's digestive secretions so changed the character of the milk that, as the digestive juices increased in quantity and strength, the work of digestion was increased, for the stronger the gastric juice became the tougher the curds became, due to a combination of the acid with the curds. (4) All milk would produce tissue, provided it differed in composition with the rate of growth of the young animal. Proteids differed in accordance to the type of digestive tract they were to develop. (5) No known method of modification would change cow's milk to human milk, and food must be sought which was suitable to develop the digestive tract. (6) A certain minimum amount of proteids, carbohydrates, fats, and mineral substances were essential for nourishment; breast milk should serve as a guide as to the amount required. (7) Milk was the proper infant food, not only because of its nutritive value, but also because it contained the only proteid that could develop the digestive tract. (8) The proteid of cow's milk was intended to develop a calf's stomach to digest grass. It must be modified to meet the requirements of an infant. (9) This might be done mechanically or chemically, by altering the character of the curds by diluting curds with alkalies or gruels. (10) When, for any reason, a sufficient quantity of cow's milk could not be taken, it should be supplemented by other forms of nucleoalbumins until the normal quantity could be digested. It was an error to feed too low proteids to overcome indigestion.

In discussing this paper, Dr. Rotch said that it was interesting and important to study the different forms of proteids, but certain practical principles should not be forgotten. In whey it was possible to obtain a high proteid, and in the caseinogen a low proteid. A child had a stomach when born, and under normal conditions would thrive with these proteids in its food. Colustrum was not milk, but an accidental secretion.

Dr. Chapin said that in whey soluble albumins were dealt with, and not nucleo-albumins, which were the tissue builders and which developed the digestive tract. It was not then physiological or a clinical advantage to use whey continually. Investigations of the future should be along the line of the proteids. It should never be considered that any modified milk was as suitable a food as mother's milk. The physician must try to keep the babies at the breast.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held May 7, 1903.

Charles L. Dana, M.D., Vice-President, in the Chair.

Leprosy.—Dr. M. B. Carleton presented a paper on this subject, which he illustrated with lantern slides. He said that in India, where he had spent some years, there were 400,000 lepers. The two great types of the disease, the tubercular and the anæsthetic, were described.

Etiology.—It was known, of course, that the specific cause of leprosy was the bacillus lepræ, but how or when

this bacillus gained entrance into the body was not known. Climatic conditions, sexual intercourse, eating of fish, were all thought to be factors in the spread of these bacilli. It could not be denied that in India, where leprosy abounded, the hygienic conditions were very poor, yet lepers were occasionally found among those who had the best of hygienic surroundings. In the parts of India in which leprosy was the most prevalent syphilis was also very common, but the speaker did not consider that there was any direct causal relation between these two diseases, believing, rather, that it was because of the lowered vitality induced by syphilis that the bacillus of leprosy gained an easier foothold in the system. Out of 2,000 cases of leprosy, 80 per cent. acknowledged having had syphilis. Touching upon the fish theory of the origin of leprosy, he expressed his opinion that the eating of fish had very little to do with the disease, because up in the Himalaya mountains, where it was impossible to get fish, leprosy was more prevalent than in the regions in which fish was eaten. Leprosy was especially prevalent between the ages of fifteen and thirty, the average being twenty-nine years, but he had seen two lepers under five years of age. The period mentioned corresponded to that of greatest liability to inoculation. However, many persons did not develop the disease until they were fifty or sixty years of age. About two-thirds of the cases occurred in men, though in some parts of India three-fourths of the lepers were men. He was unable to explain the greater susceptibility of the male sex. An attempt had been made by private individuals to remove children from their diseased parents as early as possible, and out of 600 children so removed not more than 20 per cent. showed signs of the disease. Dr. Carleton was inclined to believe that in some instances inoculation for smallpox had been the means of communicating leprosy, the custom being to make use of arm-to-arm vaccination. He had never found a case of leprosy that had been communicated from husband to wife or *vice versa*. It was not a very contagious disease; there must be direct inoculation. He had worked among them for twenty years, operating upon them, removing necrosed bone, and having his hands soiled with pus and blood from lepers, yet he had not become infected. The period of incubation was not known.

Clinical History.—Leprosy was a constitutional disease, the result of a septic poison developed through the activity of the lepra bacillus. The disease manifested itself as a general dyscrasia, characterized by certain disturbances of sensation and nutrition. For example, on the surface of the body there were areas in which the patient experienced a sensation of excessive heat, or less frequently, of icy coldness, formication or itching. In the deeper tissues there were burnings, tinglings, and other sensations, which were aggravated by motion or pressure. Ulceration and sloughing cartilage and adjacent areola tissue, ligaments, tendons, fascia, etc., occurred, leading finally to complete destruction of the part. This was most apt to occur in hands and feet. In the tubercular form the tubercles were more or less over the whole body. Death sometimes resulted from ulceration of the larynx, the form of the disease most dreaded by the natives. Lesions were sometimes found in the heart. The great majority of lepers died from some intercurrent disease, such as pneumonia or diarrhœa. Among the subjective symptoms the most marked were mental hebetude and drowsiness or languor. They hated society and suffered from diminished perception. Occasionally melancholia developed. The tradition that lepers were sterile was without foundation, and the common assertion that they were idiots was equally untrue. The disease was prone to show periods of remission and exacerbation. It was a common thing to see a leper with the finger nails at the metacarpophalangeal articulation, due to the gradual dropping off of the fingers and the contraction of the tendons. The sense of smell was affected only when the nasal cartilages were diseased. Sometimes both eyes were affected, in which case they became pitiable objects. All lepers complained of the sensation of needles and pins, sometimes spoken of as "ant bites." Lepers could not walk very far or go barefooted like the other natives. The pain was the most annoying symptom, and was often likened to the gnawing of animals. Tenderness over the spine, more especially between the scapulæ, was almost pathognomonic of early leprosy. The pulse was usually slow and compressible, but became rapid upon the slightest provocation. Among the hill tribes, who were naturally very active, this became very noticeable, because when attacked with leprosy they were unable to leave their homes. Cardiac dilatation was a common condition. The tongue was usually moist, soft and flabby, and was frequently covered with a thick white fur. It was apt to be fissured, and present tubercles, and the gums bled easily, as in scurvy. The mucous membrane of the mouth and pharynx was also the seat of tubercles, and the uvula was elongated. The body temperature was a little above the normal. The urine showed no abnormality. General malnutrition was evident, but the most marked changes were in the skin and surrounding tissues. The important complications of leprosy were anæmia, scorbutus, and syphilis. In the treatment of this disease the speaker said he had obtained fair results from ichthyol in the ulceration of the skin. Arsenic seemed to be of some benefit in the tubercular form. The different oils appeared to be of service while they were used, but as soon as they were discontinued the lesions grew worse.

A Report of the Operations of Cholelithiasis in the Service of Dr. Gerster at the Mount Sinai Hospital During the Past Five Years.—Dr. A. A. Berg read this paper, considering in it only those cases which were uncomplicated. There were ninety-eight cases and sixty-one operations, with a mortality of 18 to 29 per cent. In four cases there was an extensive gangrene of the gall-bladder. Most of the patients were emancipated, probably because of the previous prolonged attacks. To obtain good results the operation should be undertaken early. Calculi often gave no symptoms whatever, but when secondary infection of the gall-bladder occurred it would give rise to local and general symptoms. Then an operation was indicated. He did not think that inflammation of the gall-bladder should be compared to that of the appendix, for the gall-bladder, because of its elastic walls, could accommodate the inflammatory products. Immediate surgical interference was necessary in empyema of the gall-bladder, but in other cases it was better to carry the patient over to the period of quiescence. Obstruction of the common duct did not interfere with closure of the wound, but obstruction of the cystic duct did so. He preferred to make a straight abdominal incision through the right rectus muscle and fascia, then a second transverse incision just below the costal cartilage. Only one case of post-operative hernia had been encountered. The operation was never done in two stages, and a drainage tube was left in until the bile became sweet and clean. It was unsurgical to plug a fistula discharging mucus. The most unfortunate condition with which the surgeon had to contend was capillary hemorrhage occurring in connection with cholæmia. Calcium chloride had been administered before operation to these patients, but with negative effect, some of them dying from the persistent hemorrhage. Chronic jaundice seemed to cause an atrophy of the muscle in the arterioles, and the blood-pressure forced out the coagulum that formed. Dr. Berg described a new method of operating in these cases, which consisted in approaching the common bile duct from behind the duodenum, a method first suggested by Professor Kocher.

Another method, the transduodenal, had been first performed by Dr. McBurney. The danger of this operation was in the suturing of the intestine. The speaker said that he had operated upon the cadaver, opening the abdomen as usual and having the liver held up and the stomach pushed aside. At a point two inches on the right margin of the descending portion of the duodenum (rotating the latter slightly on its axis) he exposed the duct, which was incised as well as the greater hepatic omentum.

Dr. A. G. GERSTER differed with the reader of the paper as to the cause of death in cases of cholelithiasis, for, while Dr. Berg was of the opinion that septicæmia was already present, his own view was that death resulted from septic emboli being set free in the general circulation.

Dr. H. LILIENTHAL would divide these cases into two classes, those with and those without infection. He believed in taking out the gall-bladder in septic cases. During the last two years and a half he had removed about thirty-eight gall-bladders without a death, and no secondary operation had been necessary. The operation was evidently not a dangerous one.

Dr. BERG, in closing the discussion, admitted that Dr. Gerster's explanation of the cause of death was very plausible.

Proposed Legislation against Tuberculosis Hospitals.—Dr. S. A. KNOPF introduced the following resolution which was unanimously adopted:

"*Whereas*, There has been recently passed by the Legislature of the State of New York an act to amend the public health law in relation to the establishment of public sanatoria, hospitals, or camps for the treatment of tuberculosis, which act reads as follows: 'A hospital, camp, or other establishment for the treatment of patients suffering from diseases known as pulmonary tuberculosis shall not be established in any town, by any person, association, corporation, or municipality unless the board of supervisors of the county and the board of the town shall each adopt a resolution authorizing the establishment of the same;' and

"*Whereas*, If it becomes a law, it will be impossible for any city in the State or any fraternal order to establish a hospital, camp, or other establishment for the treatment of tuberculosis outside of the city limits;

"*Be it Resolved*, That the New York Academy of Medicine deeply deplores the passage of the above bill, and urgently requests His Excellency the Governor to withhold his signature to the act, which, in case it became a law, would involve the loss of thousands of lives and increase the spread of tuberculosis within the crowded districts of our cities and towns, and which would have to be considered an act of the greatest injustice to humanity."

The Operative Treatment of Rupture of the Uterus.—Kolomenkin says that the two dangers to be combated are the hemorrhage and infection, which latter is always to be regarded as already present in every case. Conservative treatment by drainage and packing is inadequate and cannot meet the necessities of the case. Complete and incomplete ruptures have the same dangers, and should be treated similarly. The methods that have been suggested are laparotomy and suture of the tear, abdominal and vaginal hysterectomy, and the Porro operation. While it is true that each of these under special circumstances may be advisable, still the most rational course of procedure, both theoretically and from the published results, is abdominal, complete hysterectomy with vaginal drainage. Improvement in the results is to be attained through greater promptness in operating and a more careful choice of operation in each case. What the limits of improvement are only time can show.—*Monatsschrift für Geburtshülfe und Gynäkologie.*

New Instruments.

A GUIDE-OBTURATOR FOR POSTERIOR URETHROSCOPY.*

BY FERD C. VALENTINE, M.D.,
NEW YORK.

THE most frequent impediment to visual examination of the posterior urethra and to local treatment of this region, is the difficulty which spasm of the compressor offers to ingression by a straight urethroscopic tube.

Paul Nogués, to overcome this difficulty, had the tips of obturators drilled with a female screw, into which he attached a short filiform guide, just as a long filiform guide is fastened to a Guyon or other sound, to convert it into a Le Fort sound. Nogués' ingenious idea is the basic one for the modification I have the honor to present.

Valentine's Guide-Obturator for facilitating posterior Urethroscopy.

The origin of my improvement is clearly due to Nogués' device, and to the practical objections it awakens.

First, no matter how well made the screw which holds the filiform and the obturator together, it always gives the operator the uncomfortable apprehension that a slight defect in manufacture may cause the instruments to separate and the filiform to escape into the bladder.

Secondly, the short, soft filiform guide being propelled by a large, long, rigid instrument, does not convey to the fingers conducting it, those delicate modifications of sensation upon which successful urethral work is predicated.

To insert a fine, soft instrument into the bladder, it alone can be relied upon to serve as a sufficient guide to prevent injury to the urethra.

The channel being traversed by a filiform bougie, impeding spasm is practically conquered, as is so often demonstrated by the use of Gouley's tunnelled catheter, Phillips', and other similar woven catheters.

To accomplish the same ends, I have designed an obturator for urethroscopic tubes, which grossly differs in nowise from the others, except in the following particulars:

The head, shaft and, handle are perforated by a straight canal, through which a 6 F. bougie will readily slide, without friction.

If then a case presents in which posterior urethroscopy is impeded by spasm, the spasm will be found to yield to a fine, soft bougie. When urethral abnormalities, pockets, or false passages prevent the ready introduction of the fine, soft bougie, the usual device of using six, eight, or even twelve, bougies at once may be employed. When by deft manipulation one has passed through the compressor, the others are withdrawn.

The filiform now traversing the entire urethra with its tip in the bladder, serves as a guide for the urethroscopic tube containing its perforated obturator. The projecting end of the filiform guide

*Presented before the American Urological Association.

is passed through the channel in the obturator, without withdrawing the guide from the bladder. When the proximal end of the filiform protrudes through the handle it may be clamped, to preclude even the very remote possibility of its being pushed into the bladder. A convenient manner of clamping the guide is with a small cravat-holder, which does not appreciably add weight to or otherwise encumber the instrument.

While the penis is supported with one hand, the tube with its obturator is inserted in the manner usual for anterior urethroscopy, until the compressor is reached. Then the tube is depressed and, guided by the filiform it contains, passed through the compressor. The obturator is then withdrawn together with the guide, leaving the tube's open tip in the posterior urethra.

The instrument requires no change in any parts of the usual urethroscopes. Indeed, the obturators now employed can be converted to the modification by having their handles and tips perforated, and hollow shafts inserted in place of the present solid ones.

These new obturators are made from my design by C. G. Heynemann of Leipzig. Their use during the past three months warrants recommending them to the profession.

Medical Items.

Contagious Diseases—Weekly Statement—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending June 20, 1903:

	Cases.	Deaths.
Measles	331	13
Diphtheria and croup	433	57
Scarlet fever	228	19
Smallpox	..	..
Varicella	90	..
Tuberculosis	283	112
Typhoid fever	50	7
Cerebrospinal meningitis	..	..

Fracture of the Base of the Skull.—E. Fossataro finds that the diagnosis of these fractures is difficult, owing to the frequent absence of symptoms and pathognomonic signs. Protrusion of brain substance occurs only in the gravest cases. To state that there is a fracture of the base, requires a careful study of the whole group of symptoms present. Traumatism of the temporal or parietal region, followed by abundant and prolonged hemorrhage from the ear of the same side, with preservation of hearing and sometimes accompanied by facial paralysis, will justify a supposition of a longitudinal fracture of the petrous portion of the temporal bone. A blow on the occipital region, followed by otorrhagia consisting of an abundant serous discharge and exceptionally of brain substance through the auditory canal, accompanied by deafness and paralysis of the facial nerve, should lead to the diagnosis of a perpendicular or oblique fracture of the petrous portion of the temporal.—*Annali di Medicina Navale.*

Dementia Præcox.—E. Bleuler says that dementia præcox is characterized by a definite kind of mental enfeeblement that is not found in any other psychic disease. The emotions, as well as the association of ideas, are attacked. There exists no line of demarcation between the various forms of the disease. This is true of any individual case as well as of the disease in general. The disease is easily differentiated, however, from other psychoses, although some ill-defined paranoidal forms may make exception to the rule.—*Journal of Mental Pathology.*

A Funeral Party in the Luchus.—On Sunday, March 1 1903, a "firing party" landed in the rain and wind for funeral services over the graves of the seven Americans buried here. Commodore Perry visited this port several times, and it was from his ships that the officers and men were buried—one officer, First Engineer Eli Crosby, from the U. S. S. *Susquehanna*, and six men from the other ships of his fleet. There are also several French naval officers interred at the same spot, one a Catholic priest and chaplain in the French navy. Our funeral party decorated the graves of all the dead Europeans with flowers and evergreens, and upon the graves of First Engineer Crosby and the sailors of our navy head-pieces and American flags were placed to mark the spot where the only Americans so far lie buried in the Luchu Islands.

Health Report.—The following cases of smallpox yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending June 20, 1903:

INDEX.

A

Abdomen, auscultation of the, in infancy, 1037; cases illustrating some important points in the diagnosis and treatment of contusions of the, 431; new stitch for closing wounds of the, 940.

Abdominal cavity, multiple cysts of the, 834; hysterectomy for myoma by Doyen's procedures, 868; pain in pleurisy and pneumonia, 883; pain, operation for abscess, 71; rigidity, diagnostic value of, 69; surgery, Fowler position in, 74; tumors, danger of delay in the case of large, 864.

Abortion, recurrent, with special reference to that form due to deficient vitality of the mother, or both parents, and often associated with some history of tuberculosis, 672.

Abscess of the cerebellum with sudden paralysis of the respiratory center, 714; of the liver following typhoid fever, 861; of the lung, a case of, 830; of the spleen, 840; periduodenal, secondary to duodenal ulcer, 427; retroperitoneal pelvic, in retrocæcal appendicitis, 867; tropical, of the liver, 507.

Absent-treatment healers in court, 782.

Absorption, influence of nephrectomy on, 238.

Accessory pancreas, 670.

Acetone, influence of varieties of fat on the formation of, 918.

Acetylene, dangers of, 400.

Achylia gastrica, 321.

Acid intoxication apparently productive of coma, 680.

Acne, postular, of the face, 591; treatment of, 120.

Acoustic nerves, disease of the, 163,

Actinomycosis in man, 1001; of the lungs, 576; of the dorsal bones, 190; sixty cases of, 788.

Acute dysenteries, 791; infectious disease, circulatory failure in, 789; yellow atrophy of the liver as a sequela of appendectomy, 788.

Adenitis, suppurative cervical, of infancy, 910.

Adenoids, analogy of trachoma to, 14; in a case of malaria, 32, 455.

Adiposis dolorosa, autopsy in a case of, 230.

Adrenal gland in relation to antitoxin production, 917; tumors, 271.

Adrenalin as a remedy for cancer, 714; treatment of surgical shock by, 877.

Adulteration of drugs, 577; of food, 458, 716.

Ælurophobia, 984.

Agricultural instruments, wounds by modern, 953.

Agriculture and malaria, 780.

Air, compressed, to enhance and prolong the action of remedies upon the cerebrospinal axis, 588; dry hot, as a therapeutic agent, 629; scientific basis of change of, 537.

Alabama, osteopaths defeated in, 422.

Alabama State Medical Association, 1025.

Albany, letters from, 168, 266, 385, 466, 709.

Albumin and casts in surgical patients, the significance of, 875; in the urine, volumetric estimation of, 632, 912; nutrition, 471.

Albuminous expectoration following thoracentosis, 256.

Albuminuria, eggs in relation to, 710; in diabetes mellitus, its importance as a factor in coma, 797; prognostic significance of, 278; traumatic, 590.

Albumosuria, 748; Bruce Jones', with peculiar nervous phenomena, 829.

Alcohol, a British symposium on the, 537; germicidal action of, 866; in infectious diseases, 916; in patent medicines, 704; medicinal value of, 498.

Alcoholism, acute, in a child aged 4 years, 868; ergot in, 516; in France, 185; international Congress against, 541; view of the alienist regarding, 901.

Alger, Ellice M., the relations and treatment of follicular conjunctivitis and trachoma, 132.

Alienists, lectures to State, 622.

Alimentary régime in mucomembranous enterocolitis, 591.

Alopecia areata, 190; congenital, 951;

Alter, Frances, paraffin injection in a case of so-called saddle-nose, 214.

Altitudes, anomalies of respiration in high, 867; differences in practice at low and high, 589; influence of, on the mortality of pneumonia 588; nervous cardiac symptoms due to, 309.

Amaurosis, acute, following infantile convulsions, 819.

Ambulance train, a German, 119.

American Academy of Medicine, the twenty-eighth annual meeting of the, 662;

American Association for the Study of Inebriety, 104.

American Electrotherapeutic Association, thirteenth annual meeting of, 463.

American Gynecological Society, 828, 919, 956.

American Medical Association, 752, 790; officers of the 795; Section on Hygiene and Sanitary Science, 795; Section on Obstetrics and Diseases of Women, 836; Section on Surgery and Anatomy, 837; Section on Practice of Medicine, 795.

American Pediatric Society, 830, 1035.

American Protologic Society, 662.

American Surgical Association, 825, 871.

Amœbic dysentery, 758.

Amygdalitis followed by appendicitis, nephritis, and endocarditis, 789.

Anæmia, causes of , in children, 226; in infancy, relation of splenomegaly in, 870, 952; infective nature of pernicious, 310; pathogenesis of progressive pernicious, 229; pernicious, 145, 323; pernicious, following thyroid enlargement, 671; plasmatic, 620; splenic, notes of a case of, 712.

Anæsthesia, shock produced by general, 749.

Anæsthetics, choice of, 840, 982; new, 680; remarks on, 924.

Anæsthetists for public hospitals, 924.

Analgesia by pure oxygen, 879.

Anasarca, essential, 30.

Anastomosos, portal, the anatomy of, 552.

Anatomy, how to study, 1.

Anders, J. M., social conditions in America in their relation to medical progress and disease, 726.

Andrews, George Pierce, notes on cases treated by venesection, 853.

Aneurysm, electrolysis in the treatment of 320; femoral, intraperitoneal sigation of external iliac for, 786; gelatin injections in, 20; of external iliac, the treatment of, by digital compression, with the report of a case, 875; of the aorta in a small boy, 380; of the aorta opening into the lung, 471; operation for the radical cure of, based upon arteriorrhaphy, 431; pathology of so-called bone, 1033; position of the heart in some cases of aortic, 819; traumatic subclavian, 980.

Angina pectoris; a criticism and a hypothesis, 550; ergot in, 516;

Angioma, racemose arterial, of frontal region, 553.

Angioneurotic purpura, 669.

Angiotribe, electrothermic, in lieu of the employment of ligatures in the open operation for the relief of varicocele, 550.

Ankylosis, cicatricial, of the jaws; a contribution to its operative treatment, 838.

Ankylostomiasis, 68, 743.

Anthracosis, a fatal case of, with autopsy, 867;

Anthrax in man, treatment of, 714.

Anthropology, attitude of the profession toward, 681.

Anthropometrical signalment, x-light in, 786.

Antrum of, Highmore, sarcoma of the; operation, 554.

Antisepsis, intravascular, 137, 146, 158; the dangers of internal, 581

Antistaphylococcus serum, 590.

Antistreptococcic serum in malignant endocarditis, 510, 879; in scarlet fever, 373.

Antitoxin and virus production, official supervision of, 742.

Antitryptic property of the blood serum in croupous pneumonia, 820.

Antityphoid serum, E. A. Wright on Macfadyen's new, 660.

Antivivisection bill in Great Britain, 583.

Anuria, the surgical treatment of, 820

Anus, cure of fissure of, without operation, 910; fissure of the, 555.

Aortic insufficiency, cardiac and cardial apex, impulse in, 787; regurgitation, 96; regurgitation with

capillary pulse, 296; stenosis with subsequent insufficiency, a case of juvenile; sudden death; autopsy, 748.
Aphasia in acute disease, with report of a case complicating smallpox, 789.
Appendicitis, 708; actinomycotic, 31; acutest form of, 389; diagnosis of, by blood examination, 591; discrepancy between clinical manifestations and pathological findings in, 427; eosinophilia in, 271; etiological relation of tonsilitis to, 267; from the standpoint of the gynecologist, 755; hemorrhagic, as the first manifestation of purpura hæmorrhagica, 207; in a woman of seventy-eight years, 954; intestinal worms in relation to, 954; leucocytosis in, 835; mortality of, 749; operative treatment of, 76; opium in the treatment of, 591, 869; oxyuris vermicuaris as a cause of, 111; pharyngitis associated with, 350; portal thrombosis in, 1005; prophylaxis of 348; retrocæcal abscess three years after operation for, 28; retrocæcal, with retroperitoneal pelvic abscess, 867; some unusual cases of, 801, 841; sudden death in, 955; subphrenic abscess complicating, 187; symptoms simulating, caused by an intra-abdominal band, 426; the serum not in Marray's dictionary 382; traumatic tuberculous peritonitis with, 868; treatment of, 185.
Appendicular dyspepsia, 480; vomito negro, two cases of, 645.
Appendix, anatomy and pathology of the vermiform, 510, 551; cancer of the, 805, 198, 433, 805, 900, 955; internal intestinal strangulation, caused by the, 801; pinworms in the, 634; primary carcinoma of, 198, 433, 955; primary sarcoma of the, 900; removal of, followed by tumor of the cæcal wall, 803; .
Army, bulk of the British, 20; medical school, 742; transport service, medical department of the, 421; women as nurses in the, 98.
Arsenic, a normal element of the living cell, 429.
Arterial pressure, prognostic and therapeutic importance of, 134.
Arteries, the traction injury of, 883.
Arteriosclerosis, 740; clinical significance of 587; early recognition of, 198; intestinal dyspepsia in relation to, 34; Trunecek's serum in, 79.
Artery, end-to-end anastomosis of the poplitical, for gunshot injury, 74.
Arthritis deformans, 797; deformans in children, 320; drainage of the knee-joint in acute supurative 750; pathology of acute rheumatoid, 778; rheumatoid, a cerebrospinal toxæmia, 280; rheumatoid, forms iodide in, 216.
Anthropathy, neuropathic, notes on a case of, 479.
Ascites, chylous, 226.
Aseptic cotton-holder, 598.
Association of American Physicians, 870, 916.
Association of Medical Librarians, 906.
Astereognosis in tabes dorsalis, 311.
Asthenia, murmur of cardiac, 788.
Asthma, from the insurance point of view, 1032; of the first sleep, 964; some new views on, 657.
Asthmatic, diet of the, 80.
Astigmatism cured by corneal trauma, 786; operative treatment of, 268.
Atavism, an alleged instance of, 343.
Ataxia, acute cerebral, 350; educational treatment of, 880; hereditary, morbid changes in, 916; without tabes, 739.
Athletics, the Columbia literary monthly on, 744.
Atmospheric pressure in the hip-joint, 629.
Atony of the duodenum diagnosticated and corroborated by operation, 866; of the stomach and gastrectasia, significance and relation of the splashing sound to, 713.
Autolysis, 511.

B

Babinski phenomenon in epilepsy, 508.
Bacillus aerogenes capsulatus, presumably the cause of extensive cavity formation in the central nervous system, 548; Shiga, in summer diarrhœa, 548, 1035; tetanus, in the blood, 551.
Back, rigidity of the muscles of the, 390.
Backache, clinical observations on, 910; in women, treatment of, 638.
Bacteria, effect of freezing and thawing on, 30; immunizing of, 540; intracellular toxins of some of the pathogenic, 549; presence of specific substances in the bodies of, 868.
Bacterial vaccines. 818; virulence, increase of, by passage in vitro, 819.
Bacteriological study of the blood in thirty cases of clinical typhoid fever, 739.
Bacteriology and epidemiology, no conflict between, 790; of cystitis, 587.
Bacteriuria, a case of, resembling Weil's disease, 632.
Balantidium coli, 472.
Bandler, Samuel Willis, some observations on vulvovaginitis in children (with special reference to the gonorrhœal form); its treatment and possible sequelæ, 401.
Bantis' disease and anæmia splenica, 590.
Barbers, sanitary regulations for, in Jersey City, 341; sanitary regulations for, in New York, 780, 815; shop, syphilis in the, 66.
Barlow's disease, 713.
Barton, Clara, may be retired, 502.
Baths, cold, importance of the reaction after, 471.
Bathycardia, 823.
Beck, Carl, the principles of protection against Röntgen-light dermatitis, 164, 223.
Becquerel rays, 260.
Beds endowed at Roosevelt Hospital in honor of Dr. Jacobi, 863.
Bee stings, rheumatism cured by 863.
Beef, diseased, sent to N. Y., 623.
Behring's antitoxin in tetanus, 551.
Bellevue Hospital, a new, 381, 461; conditions at, 219, 221, 580.
Bellevue Hospital Alumni Association, 261.
Bence Jones' albumosuria, with peculiar nervous phenomena, 829.
Benzoyl-acetyl peroxide as an intestinal disinfectant, 62.
Bequest to Manhattan Eye, Ear, and Throat Hospital, 461.
Berg, Albert A., perforating gastric and duodenal ulcers; unilateral exclusion of duodenum for perforating ulcer of its posterior wall, 885.
Bergen County (N. J.) Medical Society, 662.
Berlin, the imperial health board of, 614
Beyrout, American School of Medicine at, 66.
Beyrout, letter from, 951.
Biochemisches Centralblatt, 504.
Birth rate, decrease in the, 179.
Bishop, Louis Fangères, a hint in urinary analysis for general practitioners, 900.
Bismuth, action of, 714.
Bissell, Joseph B., a new instrument for the removal of hemorrhoids, 637.
Bile, functional disorders of the secretion of, 347; osmotic pressure of human, 672.
Bile ducts, diagnosis of affections of the, 831; present status of surgery of the, 289; surgical treatment of obstruction of the, 833.
Bilharzia, a case of, 632; in Egypt, 779; in the West Indies, 296; life-history of, 108.
Biliary calculus, reflex symptom from, 856.
Billings, Frank, medical education in the U. S., 721.
Bills, the doctor's, 500.
Birth benefit society, 1026.
Bladder, diseases of the, 1020; stone in the, geographical distribution of, 100; total extirpation of the, for papilloma, 31; traumatic rupture of the, 69; treatment of perforation of the, by transplantation, 112; ulcer of the urinary, 827.
Blastomycetes, new form of pathogenic, 940.
Blepharitis, expression of the lid margin as a therapeutic measure in, 427; marginalis, 952.
Bleyer, J. Mount, on the solarization of the nude body by the sun and electric arc light rays, and the physiological and physical influence of these rays upon iron preparations after their internal administration, 171.
Blind, passage of a bill for a commission of inquiry to investigate the condition of the adult, of N. Y. State, 662.
Blood, bacillus of tetanus in the, 551; changes in the, after extirpation of the spleen, 787; examination of the, preliminary to operation, 456; in appendicitis, 591; in malarial and other fevers, 589; in pregnancy, parturition, and the puerperium, 56; in pseudoleukæmia infantum, 473; in scarlet fever, 468; in typhoid fever, 633, 739; lance for obtaining specimens of, 225; limits to the serum test for, 356; new stain for the 1017; regeneration of the, 714; ring bodies in anæmic, 496; thermotaxis of the white corpuscles, 496.
Blood-forming organs, relation of mild infections to the, 954.
"Bloodless" surgery, 421.
Bloodletting, topical, in inflamed hemorrhoids and other affections, 145.
Blood-plates, nature and origin of, 355.
Blood-pressure, 817, 820; clinical value of, as a guide to stimulation in sick children, 391, 789; discussion on, 387; in typhoid perforations, 786.
Blood-pressure, means of controlling, 426; rise of, in later life, 510; some observations of, in adults, 391.
Blood-stain, a new, 1017; medicolegal test of, 953.
Blows, knock-out, 751.
Bodine, J. A., the radical cure of inguinal hernia with local anæsthesia, 254.
Boils, cure of, 336.

Boldt, H. J., a blood lance, 225; extra-uterine pregnancy, 46.
Bone cavities, plugging, 834.
Bones, differentiation of human from animal, 311.

Cold, disease in relation to, 12; to the spine, therapeutic value of, 96.
Colds, etiology of, 468; nature of, 268; street-car, 462.
Coley, William B , the present status of the *x*-ray treatment of malignant tumors, 441.
Colitis, chronic catarrhal, high enemas in, 912; intestinal lavage in the

treatment of mucomembranous, 869.
College of Pharmacy in Brooklyn, 222.
College of Physicians and Surgeons, New York, changes in the system of instruction at the, 461.
College of Physicians of Philadelphia, 103, 302, 422, 906, 947.
Colon and cæcum, congenital malposition of, with enclosure of ileum and cæcum in membranous sac, 875; treatment of chronic catarrh of the, 1032.
Colpeurynter, a hint in the application of the, 520.
Columbia University, department of physical education at, 423; research fellowship in medicine at, 102.
Columbus Hospital, New York, 423.
Coma, dietetic, treated by transfusion, 510; remarkable case of, apparently due to acid intoxication *sui generis*, 680; terminal. in diabetes. 587.
Compensation of physicians, 794.
Compressed air, the use of, to enhance and prolong the action of remedies upon the cerebrospinal axis, 588.
Conceptions, imperative: a study in differential diagnosis, 527.
Congenital displacement of the hip, 860; report of a bloodless reposition, followed by death, with an analysis of 23 cases in process of treatment, 818.
Congress of American Physicians and Surgeons, 821; Fourteenth International Medical, at Madrid, 715; International, of the Medical Press, 799.
Conjunctiva, primary miliary tuberculosis of the, 964.
Conjunctivitis from automobiling, 923; relation of follicular, to trachoma, 132; treatment of purulent, 196, 852.
Conner, Lewis A., report of a case of almost fatal poisoning by six grains of quinine, 535.
Constantinople, letters from, 708.
Constipation, 555.
Consumption, climate of western Texas for, 908; cures, resolution of the tuberculosis committee regarding, 222; new cure for, in Berlin, 985.
Consumptive chest, is it flat? 749.
Consumptives, model sanatorium for, 621; objection to hospital for. in Orange County, 663; sanitoria for, 511; sanatorium for New Jersey, 582; treatment of, at their homes, 281, 314.
Contagious diseases, a new hospital for, 461
Continued fever, neither malarial nor typhoid. a clinical study, 752.
Convalescent homes in public parks, 907.
Convict labor law of Illinois. 782.
Convulsions, acute amaurosis following infantile, 819; reflex, in growing boys and girls, 269.
Cook, Finley R., adhesive-plaster strapping for sprains—the indications for its use, 50.
Corneal burns, 656; diseases in children, 387; fistula, 739.
Coroner, bill to abolish the office of, 303, 417, 543.
Correspondence, Albany, 186, 266, 385, 466, 709; Beyrout, 951; Constantinople, 708; London, 23, 65, 106, 184, 230, 264, 304, 343, 384, 424, 464, 504, 584, 624, 665, 705, 745, 784, 815, 865, 907, 948, 988, 1027; New Zealand, 346; Paris, 24, 185, 344, 385, 625; Philippines, 265, 305, 345, 465, 506, 546, 585, 626, 666, 706, 746, 949, 989, 1028; Zurich, 505.
Corrosive sublimate in different dilutions, the reaction time of, against various species of bacteria, 711; poisoning from, used in a vaginal douche, 28.
Coryza, dry treatment of, 240.
Cotton-holder, an aseptic, 598.
Cough, treatment of, 395.
Cowpox, histological lesions in, 112.
Cranial form in man, 681.
Cream for the home modification of milk, 669.
Cremation, 259.
Crico-arytenoid articulation, ankylosis of the, due to acute inflammatory causes, 129.
Criminal anthropology, laboratory for the study of, at Washington, 342, 380.
Crises, gastric and intestinal, 971.
Crum, Frederick S., results of preventive medicine in Providence, R. I., 891.
Cryoscopy, 509.
Curette, danger of the, in streptococcus infection, 159.
Cutaneous affections in relation to life-insurance examinations, 479; pigmentations of genital origin in the woman, 785; tuberculosis, treatment of, 835.
Cyanosis, 189; chronic, and enlarged spleen, with polycythæmia: a new clinical entity, 871.
Cyclic vomiting in children, 548.
Cyst, dermoid, in the wall of a serous cyst of the ovary, 869; mesenteric, 679; ovarian, in a girl of eight years, 591 prerenal abdominal, simulating hydronephrosis, 788.
Cystitis, the bacteriology of, 587.
Cystoscopy, box-phantom for practice in, 952.
Cytodiagnosis: a study of the cellular elements in serous effusions; a preliminary report, 426.
Cytolysis, résumé of recent researches relating to, 241.

D

Darling, C. G., operation for carcinoma of the cæcum and one for carcinoma of the transverse colon, 938.
Deaf, pavilion for the, 814.
Deafness from disease of the acoustic nerves, 163; tobacco, 597.
Death, chief causes of. 240, 560; following a single vaginal douche, 629; the liver test for sudden, 618.
Decapsulation renal, for chronic Bright's disease, 481.
Deciduoma malignum, 594.
Decinormal salt-solution, hot, in the treatment of hemorrhoids, 415.
Defecation and urination, the psychic nature of some disturbances of the acts of, 550.
Degeneracy, physical, from environment, 437.
Delavan, D. Bryson, ankylosis of the crico-arytenoid articulation, due to acute inflammatory causes, 129.
Dementia præcox, 1042.
Demineralization, the diseases of organic, 620.
Dengue fever, 702.
Dental forceps, syphilis transmitted by, 776.
Dentist, a crazy, 422.
Denver Academy of Medicine, 582.
Dermatitis, from *x*-rays, protection against, 164, 223: iodoform, 629.
Dermatomyositis, 825, 991.
Dermatoses of the insane, 456
Dermoid cyst, 157; in the wall of a serous cyst of the ovary, 869; of the intestinal tract, 76.
Dextrocardia from pulmonary abscess, 671.
Diabetes mellitus, albuminuria in; its importance as a factor in the causation of coma, 797; case of, in a young child, 509; coma in, treated by transfusion, 510; infantile, 398; myopia as a symptom of, 631; operation in cases of, 958; pathogenesis of, 650; terminal coma in, 587.
Diagnosis, some limitations of, 641, 674.
Diaphragm, the height of the, in relation to the position of certain abdominal viscera, 551.
Diarrhœa, bacillus of Shiga in, 357, 1035, 548; chronic, 389; dyspeptic, 34; summer, of infancy, 757, 992, 1001.
Diazo-reaction in tuberculosis, prognostic value of the, 278, 588.
Diazo-reaction, work performed by the diagnosis laboratory of the department of health in connection with, 670.
Dickinson, G. K, theory and practice of spinal cocainization, 201.
Diet of the insane, 418.
Dietetic factors in health-resort treatment, 661, 819.
Digestion, arteriosclerosis affecting, 198; observations on the mechanics of, 507.
Dilatation of the right side of the heart, a case of acute, 655.
Dimethylamidoazo benzol test for free HCl in the stomach contents, limitations of the, 669.
Diphtheria, antitoxin of, death of a fœtus following an injection of, into the mother, 536; antitoxin of, in the blood of a series of 100 horses, the period of development, the time of greatest accumulation and the persistence of, 473; bacilli of, in atrophic rhinitis, 470; causes of death in, 110; complicating typhoid fever, 476; distribution of the bacilli of, 1023; head-drop following, 672; in domestic animals, 1024; the identity of human and avian, 624; intravenous injection of antitoxin in, 70; morphology of the bacillus of, 942; paralysis following, 308; specific treatment of, 491; toxic cardiac myolysis in, 787.
Diplococcal septicæmia, two cases of, 705.
Diplodocus carnegiensis, 543.
Diploma-selling institution, new, 862.
Disease, alternations in, 687; and marriage, 658; local treatment of internal, 580; self-limitation of, 226; transmitted by the public telephone, 579
Dislocations of the elbow, the operative reduction of old, 877.
Diuresis, saline, 400; through rectal irrigation, 68.
Doctor of public health, degree of, 130.
Dogs, the diagnosis of rabies in, 879; filth of, in cities. 300, 541, 710.
Domestic poisoners, 639.
Dormitory, a roof-garden, 863.
Doty, Alvah H, reappointment of, as health officer of the port of New York, 341.
Douty, Edward H., the open-air treatment of syphilis, 161.
Drainage of the knee-joint in acute suppurative arthritis, 750.
Drew, C. A., correlation of alcoholism, crime, and insanity, 976.
Drink question in London, 503.
Dropsy, a case of. the result of inflammation of the kidneys, treated by laparotomy, 750.
Drowning of patients in fecal vomit as a complication of operations during appendicitis and obstruc-

tion of the bowels, 877, 1033; sensations in, 280.
Drug habits, ergot in, 515.
Drugs, the adulteration and substitution of, 577.
Ductless glands, functions of the, 428, 457.
Duodenum, atony of the, 866; ulcer of the, followed by abscess, 197, 352, 427; ulcer of the, perforating acutely, 189.
Dwarf, anatomical study of a short-limbed, with special reference to osteogenesis imperfecta and chondrodystrophia fœtalis, 820.
Dysentery, acute, 758, 791; amœbic, 758, 994; amœbic, complicated with uncinariasis, 296; bacilli of, 429, 631; etiology of, 142, 390, 913; free receptors of the bacilli of, 311; malarial, 758; Shiga's bacillus in, 357, 742; treatment of, 336, 758; tropical, 227, 757; tropical diseases allied to, 309; tropical, the treatment of, with sulphur, 468.
Dysmenorrhœa, 23.
Dyspepsia, antiseptic in the treatment of, 136; appendicular, 480; dietary causes of, 35; etiological factors in intestinal, 670.

E

Ear, knife-blade in the, 680; treatment of suppuration of the middle, 144; use of the rotary burr in chronic suppuration of the, 279; value of symptoms referable to the, in the diagnosis of cranial injuries, 350.
Eastern Medical Society, 474.
Echinococcus cyst attached to the omentum, 843.
Eclampsia, cases of, 175, 469; chloroform in puerperal, 68; pathogenesis and therapy of, 599; prevention and treatment, 867; the circulation in puerperal, 867.
Ectopic gestation, 406.
Ectopic gestation, inhibited tubal peristalsis a cause, 836.
Ecuador, physicians in, 182.
Eczema, modern conception of, 991.
Edebohls, George M., renal decapsulation for chronic Bright's disease, 481
Edebohl's operation, a case of, 830; education legislation relating to, 259; medical, in the U S., 721, 786; modern medical, 520; preliminary to medical study, 724.
Educational commission, bill for, 662; unification, 539.
Eggs and albuminura, 710; arsenic in, 1032.
Egypt, sanitation in, 709.
Egyptian Medical Congress, 107, 142.
Ehrlich's aldehyde reaction in the estimation of putrefactive products in the urine and fæces, 833.
Einhorn, Max, cardioptosis and its association with floating liver, 647; remarks on achylia gastrica and pernicious anæmia, 321.
Elbow, ankylosis of, following gonorrhœal arthritis, 391; operative reduction of old dislocations of the, 877.
Electrical injection, treatment of lead colic by, 591.
Electricity and nerve force, identity of, 426, 701.
Electric-light bath, 69.
Electrolysis, treatment of urethral and œsophageal strictures by linear, 835.
Electrotherapeutics and quackery, 339, 386.
Elephantiasis, congenital, 111.
Ellis, A. R., fatal case of poisoning by chlorate of potassium, 776.
Ell-serum, a study of, 112.
Emboli, on the transportation of cellular, through the thoracic duct into the lungs, 509.
Emotions, maternal, in the fœtus, 540; a curious case of, 319.
Emphysema, subcutaneous, from perforation of the pleura by extension of tuberculous ulceration from the lung, 588.
Empyema, continuous aspiration for, 910; necessitatis, pulsating, 786, 918.
Enchondroma of the spinal column, 828.
Endarteritis obliterans of the central retinal artery, a case of, 842.
Endocarditis, etiology of, 145; infective, 671, 750, 879; malignant, and typhoid and paratyphoid infections, resemblances of, 786; malignant, Widal's reaction in, 985.
Endothelioma, primary, of the gall-bladder, 587.
Enemata, nutrient, 638.
England's inebriates act, 860.
Enterocolitis, mucomembranous, alimentary régime in, 591.
Enterorrhaphy, circular, 759.
Enterostomy, the value of, in peritonitis, 760.
Eosinophilos, diagnostic and prognostic significance of the, 196.
Eosinophilia in a nursing infant whose mother had a tapeworm, 913; in hydatid cysts, 714; in pelvic lesions, 271.
Epidemiology and bacteriology, no conflict between, 790.
Epidermolysis bullosa hereditaria, 1019.
Epilepsy and heart disease, the association of, 789; and migraine, relations between, 590; aura of, 959; causation of, 174, 857; cortical cell changes in, 711; medicolegal relations of, 144; paroxysmal tachycardia associated with, 120; plantar reflex in, with special reference to the Babinski phenomenon, 508; problem of, 252; salt-starvation principle in, 110; the treatment of, 469, 502, 857; treatment of, by the general practitioner, 110.
Epileptics, invulnerability of, 30.
Epileptiform convulsions, treatment of 638.
Epiphysitis, acute, of the head of the femur causing a condition simulating congenital misplacement, 838.
Epiploitis in herniotomy, 835.
Epispadias: report of a case treated by modification of Caulwell's operation, 838.
Epithelioma contagiosum of birds, 111, 350; of the hand, 270; engrafted on *x*-ray burn, 554; *x*-ray treatment of, 837, 874.
Ergot, ill effects of, 515; mode of administration of, 515; some new and unusual therapeutic applications of, 507, 514.
Erythema, angioneurotic, neurectomy for, 955.
Erythrocyte, degeneration of the, 196, 630.
Erythrophlœum, 194.
Essences, dangerous, 584.
Ether, total respiratory failure from, artificial respiration; recovery, 810.
Ethmoiditis, surgical treatment of purulent, 471.
Ethyl bromide in adenotomy and tonsillotomy, 670.
Ethyl chloride as an anæsthetic, 68, 100.
Eustachian salpingitis, electrolysis in, 268.
Everett, H. H., total respiratory failure from ether—artificial respiration for over four hours; recovery, 810.
Ewald, C. A., gastric and intestinal crises, 971:
Ewing, Charles B., observations on the plague in the Philippines and India, 521.
Examinations, New York State Medical, 462; State and County civil-service, 622.
Examiners, State boards of medical, 662.
Exanthematous eruptions, conditions modifying, 550.
Exophthalmic goiter, dermatoses in, 995; milk of thyroidectomized animals for, 349; operative treatment of, 839; treatment of, with the milk of thyroidectomized animals, 339.
Expectoration, albuminous, following thoracentesis, 256.
Extradural hemorrhage, the result of whooping-cough, operation in a case of, 711.
Extra-uterine pregnancy, bilateral, 881.
Eye, accommodation paralysis of the, 390; affections of the, complicating and resulting from rheumatism, 629; affections of the, in a hot country, 716; artificial plastic vitreous in Mules' operation, 372; imbalance and insufficiency of the muscles of the, 210; in its relation to general diseases, 910; rôle of toxins in inflammations of the, 588; successful removal of a piece of steel from the interior of the, 675; treatment of lime burns of the, 639; typhoid sequelæ affecting the, 132; recent advances in therapeutics of the, 900.
Eye-strain, headache from, 196; in youth and its modern treatment, 606.

F

Face, pustular acne of the, 591.
Facial expressions due to maladjustments of the eye-muscles, 610; palsy, the operative treatment of chronic, of peripheral origin, 818.
Fæces, estimation of indol in, by means of Ehrlich's dimethylamidobenzoldehyde reaction, 819; impaction of, complicating typhoid, 476.
Famine in Japan, 422.
Fanoni, A., syphilis in the barber shop, 66.
Fasting, therapeutic, in typhoid fever, 753.
Fat necrosis of the kidney, 754.
Fatty acids in the urine, excretion of volatile, 713.
Feeding, infant, 366; infant, results obtained in, with various forms of milk in tenements and institutions in New York, 825; infant, the breast versus the bottle in, 883; of older infants and children, 1019.
Felon, treatment of, 80, 508.
Female patients, chaste care of, 217.
Femur, acute epiphysitis of the head of the, causing a condition simulating congenital misplacement, 838; fractures of the upper third of the, 839; treatment of fractures of the shaft of the, 469.
Fever, continued, neither malarial nor typhoid, a clinical study, 752; hysterical, 591; of doubtful nature in infancy, 426; southern, 752.
Fibroid tumors, 157; Apostoli's treatment of uterine, 274; complicating pregnancy, treatment of, 828; multiple, confined to the internal plantar nerve, 776; of the broad

ligament, 430; position of the bladder in uterine, 274; treatment of uterine, 268, 275, 595, 881; uterine, 869, 884.
Filaria Bancrofti, a case of, 473.
Files, Charles O., a new high-frequency apparatus, 637.
Finger, operation without the direct use of the, 228.
Finsen light, treatment by, 258, 575.
Fischer, Louis, clinical results with antistreptococcus serum in scarlet fever, 373.
Fish and leprosy, 782.
Fistula in ano, 555; of the cornea, 739; rectal, carbonic-acid gas for, 227; treatment of urethrovaginal, 881; urinary, and carcinoma, 269.
Fixation, direct, in fractures, 428; of the prolapsed kidney, 756.
Flat-foot, mechanics of, 145.
Flexion deformity at the knee-joint, a new method of connecting, 820.
Fluorescence of quinine and other remedies in the cure of malarial fever, 782.
Fœtus, death of, following an injection of diphtheria antitoxin into the mother, 536; habitual death of the, 160; intercranial hemorrhage in, 110; maternal emotions in the, 540; rigor mortis in the, 379.
Food, adulteration of, 458, 716; factor of, in education, 943; preservatives in, 62, 510, 617, 741; proposed national bureau of, 986.
Foot-and-mouth disease, 68, 179, 461; aphthæ caused by the milk of cattle with, 1030.
Fordham Hospital plans, 583.
Forearm, dilatation of a deep vein of the, 471.
Foreign bodies in the nose, 567.
Formalin, experiments with, 299, 503, 588; in rabies, 422; in septicæmia, 137, 146, 158, 177, 227.
Fowler, George Ryerson, the toxicity of appendicitis, with a report of two cases of "appendicular vomito negro," 645.
Fracture and diastasis of the humerus with deformity relieved by operation, 841; direct fixation in, 428; necessity for more care in the treatment of skull, 838; nerve injuries following, 75; of the patella, operative treatment of, 549; of the upper third of the femur, 839; treatment of, 519.
Fraenkel, Joseph, neurofibromatosis, 925.
Framboesia in fowls, 349.
France, alcoholism in, 185; rural depopulation of, 459; triple vaccination in, 583.
Frank, Isaiah, the hereditary influence in nystagmus remarkably illustrated, 175.
Fresh-Air Society, work of the, 425.

G

Galen, the infallibility of, 661.
Gall-bladder, abnormal mobility of the, 751; contents of the, infected, with or without gallstones, 756; exploratory operations on the, 754; indications for extirpation of the, 750; is it as useless as it is dangerous? 770; necrosis of the, 1032; operative treatment of perforation of the, 71; perforation of the, complicating typhoid fever, 477; primary endothelioma of the, 587; region, some practical points in the anatomy of the, 749; rupture of the, from vomiting, 73; surgery of the, 289, 831.
Gallstones, 116; diagnosis and treatment of, 496; etiology and pathology of, 831; interesting complication in the diagnosis of, 750; multiplicity of, 348; treatment of, by cholagogues, 541.
Galvanocautery, in hypertrophic rhinitis, 479.
Galveston quarantine regulations against Cuban ports, arguments in justification of the, 814.
Ganglia, heredity of synovial, 216.
Gangrene following operation on *x*-ray cases, 553; from arterial occlusion, 911; treatment of traumatic, 376, 630.
Garbage, new rules for dealing with, 781.
Gas-ether sequence, suggestions on the, 597.
Gasserian ganglia, changes in, in neuralgia, 372.
Gastrectasia and atony of th estomach, significance and relation of the splashing sound to, 713.
Gastric carcinoma associated with hyperchlorhydria and with attacks of stupor, 817; crises, 971; digestion in jaundice, 776; ulcer, clinical, pathological and surgical phases of, 755; ulcer, treatment of, 751, 758, 789, 866.
Gastritis, chronic, in children, 187.
Gastroenterostomy, 351, 1033; for gastric or duodenal ulcers, 343; gaping of abdominal wound after, 232.
Gastrointestinal atrophy, suprarenal extract in, 1020; perforations and their diagnosis, 587; tract and upper-air passages, relation of the diseases of the, 676; tract, surgery of the, 871.
Gastroptosis, 279; operation for, 309.
Gauze, non-absorbent; the proper material for tamponades for hemorrhage, 836.
Gelatin, tetanus bacilli in, 420; treatment of hæmoptysis with, 469.
Genitals, tuberculosis of the vestibule of the female, 884.
German medical curriculum, 378.
Germany, statistics of the medical profession in, 400.
Germicidal action of alcohol, 866.
Gershel, Milton A., subcutaneous abscesses due to the gonococcus, in a child two years of age, 208.
Gerster, Arpad G., on septic thrombosis of the roots of the portal vein in appendicitis, and on pylephlebitis, together with some remarks on peritoneal sepsis, 1005.
Gestation, see *Pregnancy*.
Gingivitis, gonorrhœal, 390.
Giornale medico del regio esercito, 556
Girls, hygiene of young, 756; pelvic disease in, 756.
Glanders, death from, 502; disease resembling, in the Philippines, 19.
Glands, ductless, functions of the, 457.
Glaucoma, influence of temperature and season upon the occurrence of primary, 190.
Glioma of the brain, 235.
Glucuronic acid, excretion of, 869.
Glycerol of iodine, 630.
Glycocholate of soda, 680.
Glycogen in the leucocytes, the relation of, to infection, 820.
Glycosuria, adrenalin, 39; gravidarum, 712.
Goiter, congenital, 551; ophthalmic, see *Exophthalmic goiter*.
Gonococcus, mastoiditis due to the, 693; pneumonia, due to the, 714; stain for the, 844, 906; subcutaneous abscesses due to the, in a young child, 208.
Gonorrhœa, local treatment of, 895; yeast treatment of, in women, 137.
Gonorrhœal cutaneous ulcers, 511; gingivitis, 390; septicæmia, 876; vulvovaginitis in children, 401.
Goodsell-Bedell bill and sanatoria, 744.
Gorgas, W. C., methods of quarantine against yellow fever adopted in Havana, Cuba, during the year 1901, 83.
Goulstonian lectures on immunity, 551.
Gout, cataphoresis in, 31; colchicum in, 992; treatment of acute, 711.
Graves's disease in association with rheumatoid arthritis, 818; treatment of, 638.
Griffith, Frederic, a treatment for spina bifida, with the history of a case, 172.
Grip, relation of, to typhoid fever, 476.
Great Britain, fighting tuberculosis in, 502.
Growth of long bones, a skin lesion associated with the rapid, 824.
Guitéras, Ramón, the technique of nephropexy, with special reference to a method of attaching the kidney as nearly as possible in its normal position, 561.
Gummata, peculiar origin of, 29.
Gunshot wound of the brain, in which the Röntgen rays showed the presence of seven fragments of the bullet; localization by 5 Sweet's method made operation advisable, 877; of the stomach and intestines, toilette of the peritoneum in, 827.
Gwathmey, James T., a new inhaler, with suggestions on the gas-ether sequence, 597.
Gynecological and nervous affections, relation and co-relation of, 829.
Gynecology, massage in, 639.

H.

Hæmatomas in the new-born, two observations of multiple, 672.
Hæmaturia in chronic parenchymatous nephritis, 268; parasitic, 69; paroxysmal, 918; renal, of six months' duration without apparent lesion, 835; unilateral renal, 1020.
Hæmoglobin scale, a, 599.
Hæmoglobinuria, etiology of, 798, 880; malarial, 471; paroxysmal, 117.
Hæmolysins in human serum, 29.
Hæmolysis, union of amboceptor with the red blood cells, 229.
Hæmophilia, calcium chloride in, 389; typhoid extract in, 427.
Hæmoptysis, the gelatin treatment of, 469.
Hæmosiderin in vaccine bodies, 355.
Hæmostasis by compression and heat, 1029.
Hæmostatic action of calcium, 191.
Hair pillow, an improvised substitute for the, 120.
Halleck, Margaret S., cases of morphinism in which the drug was immediately withdrawn, 572.
Hamilton, Allan McLane, infantile insanity in its relation to moral perversion and crime, 965, 996.
Hands, disinfection of the, 389; epithelioma of the, 276.
Hartshorn, W. M., feeding of older infants and children, 1019.
Harvard University, baby hospital for, 303; health statistics of, 461; new building for the medical school, 381.
Hay fever, etiology and serumtherapy of, 511, 590; psychical element in, 494; treatment of, 144.
Head, diagnostic attitudes of the, and peculiar facial expressions caused by mal-adjustments of the eye-muscles, 610; pulsating shaking of the (Musset's symptoms), 713.
Headache, disorders of the general

health in relation to, 6; ergot in, 514; eye-strain, 196, 576.
Head-drop following diphtheria, 672.
Health authorities, conference of state and national 946.
Health boards, powers of, 622.
Health Department of New York, 542
Health-resort treatment dietetic factors in, 661, 819.
Heart, action of strychnine on the, 16; acute dilatation of the right side of the, 655; affections of the in children, 228; and blood vessels, reciprocity between the, 688; arteriosclerotic lesions of the, 198; dilatation of, at puberty, 16; disease of, and epilepsy, association of, 789; drugs in dilatation of the, 1003; ergot in diseases of the, 515; hypertrophy of the, in nephritis, 190; influence of marriage and pregnancy on, diseases of the, 508; life insurance, in relation to the, 496; low (bathycardia), 823; nervous affections of the, due to high altitudes, 309; position of the, in some cases of aortic aneurysm, 819; ruptured aneurysm of the mitral valve, followed by death from cerebral embolism, 116; small, malnutrition with a, 117; spontaneous rupture of the, 188; stimulants of the, 267; suture of the, for incised wounds, 307; tuberculosis of the, 818; wandering, 269; weakness and dilatation of the, due to chronic nutritional diseases, 757.
Heat in the treatment of external tuberculosis, 834; physiological and clinical study of animal, 229; to the spine, therapeutic value of, 96.
Heat-stroke, 656.
Heberden's nodes, etiological significance of, 308.
Hedonal, observations upon the hypnotic action of, 800.
Hemianæsthesia alterans, 470.
Hemianopsia, report of a case of monocular inferior, 711.
Hemorrhage, citric acid in uterine, 680: extradural, the result of whooping-cough, operation in a case of, 711; ergot in, 28; spontaneous, in the new-born, 226; thyroid extract in, 427; treatment of gastric and duodenal, 396, 748.
Hemorrhoids, 554; a new instrument for the removal of, 637; hot decinormal salt-solution in the treatment of, 415; injection treatment of, a failure, 555; local bloodletting in, 145; treatment of, 387.
Henry, A. G., non-operative treatment of chronic mammary tumor 899.
Hepatitis, a case of, with grave icterus in an infant nursed by a nephritic mother, 591.
Heredity of mental diseases, 579; some questions in, 81, 114.
Hermaphroditism, a case of true, 350.
Hernia, esthetic treatment of, 834; fatty inguinal, 229; inguinosuperficial, 52; oblique inguinal, 73, 711; radical cure of femoral, 834; radical cure of inguinal, in infants and young children, 749; radical cure of umbilical, 760; radical cure of inguinal, with local anæsthesia, 254; results of operation for the radical cure of inguinal and femoral, with analysis of 1,000 cases operated upon between 1891 and 1902, 874; strangulated, in an infant six weeks old, 748; strangulated, with gangrenous appendix, 802; umbilical, rupture of skin in, 1004.
Herniotomy, epiploitis in, 835.
Heroin habit, another curse, 639.
Herpes, the pathology of labial, nasal and body, occurring in acute croupous pneumonia, and their relation to the so-called herpes zoster, 673.
Hetol, treatment of tuberculosis, by, 713.
Hibbertia volubilis, 909.
High-frequency apparatus, a new, 637; electricity in medicine, the use and abuse of, 644.
Hip, congenital displacement of the, 860; disarticulation of the, for sarcoma of the femur, 73; disease, senile, 226; rôle of atmospheric pressure in the, 629; treatment of congenital dislocation of the, 818, 911.
Hirschman, Louis J., a study of the rectum, with reference to the causative factors of obstipation, 767.
Hodgkin's disease and arsenical poisoning, 868; *x*-ray treatment of, 341.
Hogsett, C. Y., an aseptic cotton-holder, 598.
Hollen, Henry B., ocular symptomatology in diagnosis, 773.
Homœopathic Medical Society of the State of New York, 288.
Horses, hydrophobia among, 542.
Hospitals, bequests to, 781; for sailors athome, 663; in Philippine mountains, 663; medical men as trustees of, 902, 983; nurses, strike of, 422; privileges for homœpathic physicians in, 863.
Hot climates, malaria and malignant diseases in, 520.
Houghton, E. R., death of a fœtus following an injection of diphtheria antitoxin into the mother, 536.
Humerus, fracture diastasis of the, with deformity relieved by operation, 841.
Hunt, J. Ramsay, neurofibromatosis, 925.
Hutchinson, Woods, is the gall-bladder as useless as it is dangerous? 770.
Hydatid cysts, eosinophilia in, 714; of the abdominal cavity, multiple, 834; of the mesentery, suppurative, 787; of the spleen, 509.
Hydrocele, removal of, intact, 157.
Hydrocephalus complicating labor, 775.
Hydrogen dioxide, action of, on pus, 40.
Hydronephrosis, congenital, 40; intermittent calculous, 30; pathogenesis of intermittent, 440.
Hydrophobia among horses, 542; run to earth, 866.
Hydrosalpinx, torsion of, during pregnancy, 112.
Hygiene, military, in the tropics, 460; of young girls, 756.
Hyoscine in morphinism, 427.
Hyperacidity, gastric (hyperchlorhydria); its nature, diagnosis, and treatment, 713.
Hypernephroma, 76.
Hyperpyrexia, puerperal, of malarial origin, 672.
Hypnotics, some dangers of, 672, 860.
Hypnotism, a German view of, 221.
Hypodermoclysis, 388; in pneumonia, 268.
Hysterectomy, abdominal, for myoma by Doyen's procedures, 868; for large fibroid tumors, 829; for malignant disease and procidentia, 594; or myomectomy, 828; technique of abdominal, 881.
Hysteria, 883; favorable action of nitrite of amyl on, 788; simulating general paralysis, 480.
Hysterical fever, 591.

I

Ichthyol for anal fissure, 555.
Idiocy, amaurotic, 429.
Ileus from thrombosis of the mesenteric vein, 390.
Iliac artery, intraperitoneal ligation of external, for femoral aneurysm, 786; treatment of aneurysm of the external, by digital compression, 875
Illinois State Medical Society, 882.
Imitation, suggestion, and social excitement, 28.
Immigration, immense increase in, 543, 854; problems of, in Great Britain, 983.
Immunity and cancer, 732; artificial, in experimental tuberculosis, 823; in recovery from pneumonia, 787; theories of, 241, 551.
Immunizing of bacteria, 540; the human organism against tuberculosis, 716.
Imperative conceptions: a study in differential diagnosis, 527.
Index medicus revival of the, 104, 987.
Indian Territory, regulation of the practice of medicine and surgery in, 459.
Indiana, smallpox in, 541.
Indiana State Medical Society, 1026.
Indol, the estimation of, in the fæces by the means of Ehrlich's dimethylamidobenzoldehyde reaction, 819.
Inebriates, legislation regarding, in Great Britain, 220, 860
Infancy, fevers of doubtful nature in, 426; summer diarrhœas of, 757; synopsis on some of the renal lesions in, 830.
Infant, a case of floating kidney in an, 510; feeding, 366; feeding, observations upon results obtained in, with various forms of milk in tenements and institutions in New York 825; feeding, principles of, 1039; feeding, the breast versus the bottle in, 883; one month old, morphine poisoning in an, 720.
Infantile paralysis, tendon transplantation in, 319; paralysis, treatment of, 789; paralysis, treatment of the neglected results of, 320.
Infantile scorbutus, 631.
Infected gall-bladder contents, with or without gall-stones, 756.
Infections, changes in the uterus in the course of acute, 675; systemic, due to natural teeth conditions, 548.
Infectious diseases, some points on the management of, 468; tendency to contract, in the prisoner and the free man, 86.
Inflammatory diseases, acute, ergot in, 515.
Influenza, 631; hyperpyrexia after, 71; nervous form of, 29; relation of atmospheric pressure to, 188; unrecognized, 71.
Inhaler, a new, 597, 622.
Inheritance of syphilis, 699.
Insane, administration of the State hospitals for the, 97; burning of a London asylum for the, 304; care of the, 194; care of the, in New York State, 298, 1024; dermatoses of the, 456; diet of the, 418; segregation of the, 783; tent life for the tuberculous, 17.
Insanity, contagious, 456; correlation of, with alcoholism and crime, 976; delusional, complicating pulmonary and laryngeal tuberculosis, 612; in the German army, 943; increase of, in Great Britain, 257; infantile, 965, 996; puerperal, 337. 337.
Insects as carriers of infection, 388.

Insomnia, ergot in, 514.
Inspector, an act to create the office of medical, 542; reduction of the salary of State medical, 623.
Instruments, sterilization of, 219.
Insurance, infant life, 659; law of New York State, an amendment to the, 543.
Internal secretions, reciprocity between the, 688.
International congress against alcoholism, 541.
International Congress of the Medical Press, 799.
International Medical Congress, the Fourteenth, 690, 699, 715, 816; history of, 147; Section on Internal Medicine, 878; Section in Surgery, 834.
Intestinal absorption, effect of cocaine on, 30; crises, 971; defects, transplantation of omentum in the operative treatment of, 670; disorders, fasting in, 1030; dyspepsia, etiology of, 33; indigestion, relation of, to arteriosclerosis, 145; localization, 876; obstruction following abdominal contusion, 76; obstruction, gastroenterostomy for, 351; obstruction, limitation of non-surgical treatment in, 757; obstruction, the pathology and treatment of, 877; occlusion, diagnosis of, 714; perforation complicating typhoid, 476, 477; resection, 759; resection and end-to-end anastomosis with the O'Hara forceps in a case of tuboovarian abscess with appendicitis, 549; strangulation, internal, from an elongated inflamed appendix, 801
Intestine, congenital dilatation of the, 271; dermoid cysts of the, 76; foreign body in the, 32; growth of bacteria in the, 71; mechanism of strangulated, 350; perforation of the, by a worm, 387; resection of, 615; successful removal of 265 cm. of gangrenous, 680; siphon action of the, 31, 260.
Intranasal obstruction and its treatment, 567.
Intussusception in a baby, 347; reduction of, 536; reduction of, by water pressure, 479; result of operation for, 633; three cases of, in the same family, 189.
Iodine reaction, significance of the, 196.
Iodoform, dermatitis from, 629; intoxication, psychosis due to, 499.
Iritis, diagnosis and treatment of, 964; ergot in, 514; nasal origin of, 673; rheumatic, 948.
Iron, influence of light upon, after its internal administration, 171.
Isaacs, A. E., resection of intestine, with report of three interesting cases, 615.
Ischiorectal abscess, 555.
Isolysins in the serum of disease, 953.

J

Jackson, George Thomas, the treatment of ring-worm, 575.
Jacobson, Nathan, hemorrhagic appendicitis as the first manifestation of purpura hæmorrhagica, 207.
Janeway, Edward G., observations on some limitations of diagnosis, 641.
Japan, famine in, 422.
Jaundice, gastric digestion in, 776; treatment of catarrhal, 880.
Jaw, cicatricial ankylosis of the, 838; sarcoma of the, 312; tuberculosis of the, 955.
Jewey, J. Wilkinson, the etiology and prevention of senile cataract, 333.
Jewish Hospital Association, convention of the, 222.
Joints, temperature of chronically diseased, 954.
Jonas, A. F., cancer and immunity, 732.
Jorgensen, P. P M., a case of acute dilatation of the right side of the heart, 655; a case of eclampsia, 175.
Josephson, J. C., a case of adherent placenta retained and discharged after a long process of decomposition—recovery, 898.
Juvenile tabes, and its relation to hereditary syphilis, 751.

K

Keen, W. W., the American School of Medicine at Beyrout, 66.
Kelly, Howard A., the expansion of a specialty, 693.
Kevin, R. O., the local treatment of acute and chronic gonorrhœa, 895.
Kidneys, a case of dropsy, the result of inflammation of the, 750; affections of the, in estivo-autumnal fever, 376; attachment of, as nearly as possible in its normal position, 561; congenital single (unsymmetrical), 698; decapsulation of the, 917; decapsulation of the, for puerperal eclampsia, 921; disease of, simulating stone, 910; fat necrosis of the, 754; fatty tissues surrounding the, 227; fixation of movable, 398, 756; floating, in an infant, 510; importance of hyaline casts in the diagnosis and prognosis of diseases of the, 79; movable, 467; rupture of the, 270; symptoms and diagnosis of stone in the, 751; treatment of suppurative inflammation of the, 428; vesical appearances of suppuration in the, 144.
Kime, J. W., phototherapy and photographing through the body, 65.
King Edward's sanatorium for tuberculosis, 141.
King, Ferdinand, a new suspensory bandage, constructed on anatomical lines, 636.
Kissing, legislation against, 223.
Kleptomania and collectivism, 56.
Knapp, John Rudolph, successful operation for the radical cure of complete prolapse of the rectum, 896.
Knee-joint, a new method of connecting flexion deformity at the, 820; neuromimesis of, simulating tuberculous disease, 776.
Knock-out blows, 751.
Knopf, S. A., the treatment and care of consumptives at their homes, and the urgent need of local sanatoria, 281, 314.
Kohn, Samuel, a case of sepsis following an attack of osteomyelitis from a slight cause, 93.
Kohnke, Quitman, mosquitos, quarantine, and some statistics with regard to yellow fever, 410, 950.

L

Laache, S. B., reciprocity in pathology, 687.
Labor, aseptic, 999; complicated by hydrocephalus, 775; complicated by tumor, 655; essentials of aseptic, 910; premature, in typhoid fever, 869; spurious, 310.
Laboratories of the Philippines, report of the government, for 1902, 702.
Laboratory diagnosis and the general practitioner, 619.
Lacerations of the cervix: when shall they be repaired? 756.
Lactation, prolonged, 995.
Lambert, Walter Eyre, trachoma in the public schools of New York, 293, 316.
Lamps, new, for phototherapy, 586.
Laparotomy, hernia following, 215.
Laporte, George L., a new blood-stain, 1017.
Larynx and velum palati, tumors of the, 591; ankylosis of the cartilages of the, due to acute inflammatory causes, 129; inherited diaphragm of the, 111; operative treatment of stenosis of the, following intubation and tracheotomy, 748; syphilis of the, 144; treatment of tuberculosis of the, 787; tuberculosis of the, and pregnancy, 470.
Lavage, intestinal, in the treatment of mucomembranous colitis, 869; technique of gastric, 240.
Lead colic, treatment by electrical injection of, 591; paralysis, central origin of, 391; poisoning in an infant, 912; poisoning, the structural changes which occur in experimental, 869.
Lecithin, weight of, in milk, 191.
Lectures, the value of, 690.
Leg painless amputation of the, after the intraneural injection of cocaine, 749.
Legacies to charity, 503.
Lemon-juice, bactericidal action of, 21, 63, 104.
Leper colony in the Philippines, 266.
Leprosy, 1039; and fish, 782; diagnosis of, 952; in Japan, Iceland, and Norway, 779.
Leszynsky, William M., headache in its relation to disorders of the general health, 6.
Leucocytes, glycogen reaction of the, 216, 1032; proportion of the, in pregnancy, labor, and the puerperium, 216.
Leucocythæmia, acute, 96.
Leucocytosis in appendicitis, 835; meaning and significance of, 128, 748.
Leucoplasia in secondary syphilis, 992.
Leukæmia, a clinical and pathological study of two cases of splenic, 870; acute lymphatic, 870; associated with tuberculous mesenteric glands, 396; Löwit's bodies in myelogenous, 1032; myelogenous, with absence of eosinophiles, 995; report of an autopsy and the microscopic findings in a case of acute, 870.
Levene, P. A., the biological relationship of proteids, and on proteid assimilation, 495.
Levien, Henry, tuberculous (basilar) cerebrospinal meningitis and delusional insanity complicating pulmonary and laryngeal tuberculosis, 612.
Life-insurance, cutaneous affections in relation to, 479; the heart, in relation to, 496.
Ligatures, device for holding, 270; sterilization of catgut, 925.
Lime burns of the eye, treatment of, 639.
Lincoln Hospital, 63.
Lipoma arborescens, 507.
Liquor, the sale of, in Russia, 662
Lister jubilee, 22, 59.
Literature, the doctor in, 101.
Lithiasis, renal, 638.
Liver, abscesses of the, following typhoid fever, 477, 861; acute atrophy of the, as a sequela of appendectomy, 788; cirrhosis of the, 552, 673; enlargement of the left lobe of the, due to cirrhosis, 232; floating, association of, with cardioptosis, 647; functional power of in children,

as determined by experimentation with levulose, 430; lesions of the, from cocaine, 112; palpation of the, 200; primary cancer of, in a girl aged twenty-one years, 760; prognosis of atrophic cirrhosis of the, 470; test for sudden death, 618; treatment of diseases of the, 176; tropical abscess of the, 348, 389, 507.
Livingston County (N. Y.) Medical Society, 986.
Local treatment of internal diseases, 580.
Locomotor ataxia, treatment of pains of, 203.
Lofton, Lucien, hot decinormal salt-solution injections in the treatment of hemorrhoids, 415; housing of the poor in, 501.
London, drink question in, 503; letters from, 23, 65, 106, 184, 230, 264, 304, 343, 384, 424, 464, 504, 584, 624, 665, 705, 745, 784, 815, 865, 907, 948, 988, 1027.
Longitudinal sinus, gunshot wound of the, 1033.
Loomis, Henry P., a comparative study of the routine treatment of certain diseases in four of the large New York hospitals, 41.
Loree, Dean, operation for carcinoma, of the cæcum, and one for carcinoma of the transverse colon, 938.
Lorenz, Dr. Adolph, in England, 182.
Louisiana quarantine, 662.
Louisville Academy of Medicine, 1025.
Lunacy increase of, in London, 544; increase of, in Scotland, 904.
Lung, abscess of the, 830; actinomycosis of the, 576; gangrene of the, cured by operation, 995; infarction of the, 919; knife-blade removed from, 788; rare murmur in the, 751; surgery of the, 74, 629; surgical treatment of gangrene of the, 955.
Lupus erythematosus, relation of, to tuberculosis, 109, 511; x-ray and Finsen light in the treatment of, 575.
Luxations, spontaneous, in convalescence, 31.
Lying-in Hospital of New York, new building of the, 18.
Lymphadenoma, associated with recurrent fever, 320.
Lymphatic leukæmia, acute, 870.
Lymphocytosis, spinal, and ocular affections, 869.

M

Maccarty, Dr. Thaddeus, an account of, 507.
McChesney, H. F., auto-epidermic skin-grafting, 937.
McGill University, faculty of veterinary medicine dissolved at, 704.
McGraw elastic ligature, a preliminary report on some experiments with the, 556.
Maclagan's gift to humanity, 703.
Maddin, Thomas L., a banquet in honor of, 583.
Maine Medical Association, semi-centenary of the, 906.
Malaria and agriculture, 780; and malignant diseases in hot climates, 520; and quinine, 621; and yellow fever, 500, 791; etiology and prophylaxis of, 880; kidney complications in, 376; methylene-blue in the treatment of malignant, 868; microscopical diagnosis of, 146, 631; new factor in the etiology of, indicating new methods of treatment, 812; nomenclature of, 360; post-operative, 291; puerperal hyperpyrexia due to, 311; quartan, 38; report of the Liverpool School of Tropical Medicine, 986; soil nitrification affecting, 993; typhoid form of, 336; with adenoids, a case of, 455.
Malarial and other fevers, the diagnostic value of blood counts in, 589; dysentery, 758; parasite, a new stain for the, 819; vertigo, 267.
Malta fever, 594.
Mammary carcinoma, primary and recurrent, treated by the x-ray, 845; gland, tuberculosis of the, 839.
Man, the study of, 135.
Manhattan Eye, Ear, and Throat Hospital, bequest to, 461.
Manhattan State Hospital, 539, 582.
Manila, cholera at, 744; hospital for, 305; isolation hospital for the Chinese in, 949; water-supply at, 949.
Manubrial dulness, especially as related to enlarged bronchial glands, 712.
Marriage and disease, 658; and pregnancy, influence of, on diseases of the heart, 508; relation of, to mortality, 57.
Marshall, G. G., a case of carbolic acid poisoning, 174.
Masked fever, a rare form of, 471.
Massage in gynecology, 639.
Mast cells versus clasmatocytes, 71.
Mastitis complicating typhoid, 476.
Mastoid operation, indications for the, 413; variations in the course of a facial nerve in relation to, 905.
Mastoiditis, 593; due to the gonococcus, 693; treatment of acute, 1002; treatment of, 1020.
Maternal emotions in the fœtus, 540; impression superstition, 212.
Matheny, R. C., imbalance and insufficiency of the eye muscles, 210.
Matteawan State Hospital, report of the, 1023.
Maxilla, diffuse hypertrophy of the, 471; excision of the superior, under medullary narcosis, 508.
Mayo, William J., the present status of surgery of the gall-bladder and bile-ducts, 289.
Measles, a rare case of, 751; peritonitis following, 256; secondary eruption in, 951.
Meat, danger of preserved, 30; diet, effects of, 112.
Meconium, the relation of, to the fetal appendix, 819.
Mediastinitis, purulent, 134.
Mediastinum, surgery of the posterior, 834.
Medical colleges, educational requirements for admission to, 724, 903; curriculum, the German, 378; education, modern, 520; ethics of the American Medical Association, 792; institutions, the duties and responsibilities of trustees of, 823; practice law in New Jersey, 622; practice law in Pennsylvania, 223; profession as a career, 218; profession, how to remedy the evils of the, 668; progress and disease, social conditions in America in their relation to, 726; reciprocity between the States of the Union, 726; services rendered the State, compensation for, 859; societies, how to increase membership in, 386.
Medical Library and Historical Journal, 102.
Medical Society of the County of New York, 77, 396, 557, 1001.
Medical Society of the State of New York, 192, 266.
Medicine and surgery, applied, 723; progress of modern, 498; scientific, 722.
Medicines, alcohol in patent, 704; proposed national bureau of, 986; registration of patent, 710.
Medicolegal port-mortem examinations, 589.
Melanoma in a cow, 38.
Melanotic tumor of skin: ganglionic invasion of slow progress, 430.
Meningeal hemorrhage, diagnosis of, 1027.
Meningitis, fatal, with myosis and salivation as the only symptoms, 711; from the coli-bacillus, 66; on receiving ship *Minneapolis*, 863; recovery from tuberculous, 469; tuberculous, association of, with typhoid fever, 412; tuberculous, complicating pulmonary and laryngeal tuberculosis, 612; tuberculous, following pulmonary tuberculosis, 296.
Meningocele, 39.
Meningococcus, cultures of the, 235.
Menstrual disturbances, treatment of, 638; pain in the intervals, 109; suffering, and the action of permanganate of potash therein, 576.
Menstruation, weight wave of, 992.
Mental disease, arteriosclerosis in relation to, 198; disease, heredity of, 579; functions, relation of the prefrontal lobes to the, 227; vision, the loss of, 495.
Mephitis mephitica, the erythrogenic spleen of, 112.
Mercurial injections, the question of, 269; preparations, disinfecting power of the old and new, and phenol, 590; reaction of the oral mucous membrane in syphilitics, 600.
Mercury, an alleged cause of tabes, 590; in syphilis, 426.
Mesenteric cyst, 679; cyst, suppurative hydatid, 787; vein, varix of the inferior, complicated by chronic ulcerated colitis, 838.
Metatarsalgia, electricity in, 229.
Methylene-blue in the treatment of malignant malarial fever, 868.
Metric system, use of the, in the United States, 319.
Mettler, L. Harrison, imperative conceptions: a study in differential diagnosis, 527.
Meyer, Alfred, on a case of complete fibrous obstruction (congenital?) of both superior and inferior venæ cavæ in a young man of eighteen years—first recorded case, 806.
Micrococcus catarrhalis, cultures of the, 235; of acute rheumatism, 618.
Microorganisms of disease as weapons in warfare, 945.
Middle ear, does early treatment of acute inflammation of the, prevent the more serious complications? 480; suppuration, chronic, 592.
Midwifery, legislation on, 381.
Migraine and obstipation, 460.
Military hospitals and female nurses, 62; service, character study in the examination of persons for, 578; hygiene in the tropics, 460.
Milk, chemical analysis of mixtures, 1036; diet in nephritis, the dangers of exclusive, 882; estimation of fat and solids in, 1037; examination of, by the general practitioner, 196, 532; home modification of, 366, 669; influence of preservatives upon the food value of, 19; of cows which have reacted to the tuberculin test, infectiveness of, 858; raw, and formaldehyde, note on the detection of, 551; therapeutic properties of the serum of, 878, 1033; significance of streptococci in, 309.
Milk-supply, relation of infant mortality to the, 300.

Milk-warmer, an emergency, 224.
Minchin, David J., reduction of intussusception, 536.
Mississippi State Medical Association, 1025.
Missouri State Medical Association, 423.
Molluscum, contagiosum and psoriasis, the local treatment of, 671.
Moore, John T., post-operative malaria, with a report of two cases, 291.
Morphine, anti-serum for poisoning by, 66, 994; poisoning by, in an infant one month old, 720.
Morphinism, cases of, in which the drug was immediately withdrawn, 572; hyoscine in, 427.
Morrison's operation, 553.
Morrissey, J. J., essential and paroxysmal tachycardia, 204.
Mortality in appendicitis, 749; post-operative, 834; reduction of infantile, 1001.
Morton, William James, primary and recurrent mammary carcinoma treated by the *x*-ray, 845.
Moschcowitz, Alexis V., inguino-superficial hernia, 52.
Mosquitos as carriers of disease, 587; blood-sucking, 119; in relation to yellow fever, 410, 950; on vessels, 582; quarantine in relation to, 628; sanitary aspect of, 427; soil nitrification in relation to, 993.
Motor function, the results of the experimental exclusion of the, 439.
Mount Sinai Hospital Alumni Association, 183.
Mouth, infection in the, due to natural teeth, 550; mercurial reaction of the mucous membrane of the, in syphilitics, 600.
Mouth-breathing, control of, at night, 227.
Mucomembranous enterocolitis, alimentary régime in, 591; intestinal lavage in the treatment of, 869.
Mules' operation, plastic artificial vitreous in, 372.
Multiple sclerosis and tabes, association of, 712.
Mumps at Columbia College, 622.
Munger, Carl E., a classification of intranasal diseases for use in teaching, 899.
Murmurs, diastolic, without valvular lesions, 955; murmur in the lung, a rare, 751; of cardiac asthenia, 788; presystolic mitral, complicating pregnancy, 919.
Muscle metabolism and oxygen, 479.
Music as a therapeutic agent, 622.
Musset's symptoms, 713.
Mydriatic after the age of forty-five years, the use of a, 711.
Myocarditis in children, 953.
Myolysis, toxic cardiac, in diphtheria, 787.
Myoma, abdominal hysterectomy for, by Doyen's procedures, 868; complicating pregnancy, 828; sarcomatous degeneration of, 836.
Myomectomy or hysterectomy, 828
Myopia as a symptom of diabetes mellitus, 631.
Myositis ossificans, 1033; ossificans, traumatica, 876
Myxœdema in a child, 1037.
Myxomata, nasal, treatment of, 571.

N

Nævi, arterial and capillary, in affections of the liver and biliary passages, 430; of the oval cavity, congenital, 553; of the scalp and nose, treated by hot water injections, 748; treatment of, 76.
Narcosis, excision of the superior maxillary under medullary, 508.
Nasal deformity corrected by paraffin injections, 841; diseases, and pulmonary disease, relation between, 478; origin of general septic infection, 776; septum, perforation of the, in workers in chromate factories, 111.
Navy, increase of the medical corps of the, 664; medical officers of the, 979; need of young surgeons for the, 583; statistical report of the health of the British, 640.
Necrosis, fat, of the kidney, 754.
Negroes, cancer among, 437; tuberculosis in, 798.
Neoplasm of the pylorus, 787; prevention of, by physicotherapy, 881.
Nephrotomy, influence of, upon absorption, 188, 238.
Nephritis, cardiac hypertrophy in, 190; chronic diffuse, without albuminuria, 900; dangers of exclusive milk diet in, 882; diagnosis of chronic interstitial, based upon physical signs, chiefly cardiovascular, 800; freezing-point of the urine in, 912; in a four-year-old boy having only one kidney, 830; parenchymatous syphilitic, 111, 631; scarlatinal and diphtheritic, 350; surgical treatment of, 754; treatment of nervous phenomena in chronic, 181; venesection in acute, 96.
Nephrolithiasis due to uric-acid calculi, the administration of calcium salts in, 548.
Nephropexy, the technique of, with special reference to a method of attaching the kidney as nearly as possible in its normal position, 561.
Nephroptosis, heredity of, 389.
Nephrotoxins, 917.
Nervous and gynecological affections, relation and corelation of, 829; and mental diseases, diagnostic and prognostic data in, 936; system, reciprocity of the, 688.
Nervousness, prevention of, 267.
Nerves, changes in peripheral, produced by toxic substances applied to the skin, 719; energy, is it electricity? 701; force and electricity, the identity of, 426; injuries to, following fractures, 75; or trophic areas and carcinoma, a possible relationship between, 713; vasomotor, 238.
Neuralgia, blue light for, 905; injections of sterilized air in, 191; of the fifth pair, subdural implantation of rubber tissue in operation for inveterate, without removal of the Gasserian ganglion, 827.
Neurasthenia, in children, 1026; meaning of the term, and its etiology, 672; treatment of, 312.
Neurectomy, intracranial, 113.
Neuritis, general pathology of peripheral, 312; multiple, of uncertain origin, 308.
Neurofibromatosis, 925.
Neuromimesis of knee simulating tuberculous disease, 776
Neuropathic arthropathy, notes on a case of, 479.
New Orleans, insanitary condition of, 261, 709.
New York Academy of Medicine, 156, 313, 392, 432, 512, 552, 592, 676, 1041; Section in General Medicine, 33, 393, 959; Section on Obstetrics and Gynecology, 274, 434, 594; Section on Pediatrics, 32, 117, 353, 633; Section on Surgery, 232, 351, 553, 677.
New York City, medical inspection of schools in, 428; rapid growth of, 744.
New York County Medical Association, 36, 157, 277, 398, 514, 999.
New York Eye and Ear Infirmary strike of nurses at, 422.
New York Hospital, legacy to the, 382.
New York Pathological Society, 38, 234, 355, 472, 632.
New York Psychiatrical Society, 423, 996.
New York State Board of Health, 261; Hospital for the care of crippled and deformed children, 462; medical examinations, 462; proposed union of medical societies in 185, 193.
New Zealand, letter from, 346.
Newborn, infections in the, 1036; pyogenic infection in the, 32; respiratory disturbances in the, 1039; spontaneous hemorrhage in the, 226; two observations of multiple hæmatomas in the, 672.
Newsboys' homes, 781.
Nicoll, Henry D., memorial address on the late Dr. T. Gaillard Thomas, 1015.
Nitrite of amyl, favorable action of, on hysterical manifestations, 788.
Nitrous oxide and ether inhaler, a preliminary note on a new, 622.
Nose, anatomical method of demonstrating the accessory cavities of the, 940; classification of intranasal diseases, 899; intubation of the, 1040; local use of cocaine in the, 867; obstruction of, and its treatment, 567; subcutaneous injections of paraffin for deformities of the, 553, 840; throat, and thoracic cavity, some relations between diseases of the, 676.
Nucleoalbumin, significance of, 278.
Nurses, antiseptic rules for monthly, 668; in England, pension fund for, 584; legal registration of, 141; of the Presbyterian Hospital, home for, 542; strike of hospital, 422; trained, meeting at Albany, 662.
Nystagmus, hereditary influence in, 175.

O

Oak, poison, on the active principle of, 855.
Oatman, E. L., plastic artificial vitreous in Mules' operation, 372.

Obstetric suggestion, an, 787.
Obstipation, causative factors of, 767; migraine in relation to, 460.
Obstruction, intranasal, and its treatment, 567.
Occlusion, intestinal, rare case of, 430.
Ocular headaches, 576; symptomatology in diagnosis, 773.
Œdema, acute pulmonary, treatment of, in young children, 634; pulmonary, ergot in, 515; thirty cases of epidemic, 134.
Œsophagoscopy, the diagnostic value of, 880.
Œsophagus, etiology of carcinoma of the, 869; surgical treatment of stricture of the, 390.
O'Hara forceps in intestinal resection and end-to-end anastomosis, 549.
Omentum, chronic productive inflammation of the, without apparent cause, 843; echinococcus cyst attached to the, 843; transplantation of, in the operative treatment of intestinal defects, 670.
Omphalocele, 274.
Opdyke, Ralph, the close analogy of trachoma to adenoids, 14.
Operation, preparation of patient for, and the relative value of the blood examination, 456; without the direct use of the fingers, 228.
Opium, ergot in poisoning by, 514, 516; in appendicitis, 591, 869; in surgery, 549.
Optic atrophy, the treatment of, 883; nerve, tuberculosis of the, 190.
Oral cavity, congenital nævous formation of, 553.
Organacidia gastrica, additional notes on, 550.
Organism as a unit, 689.
Organisms, ultra-microscopic, 790.
Organs, reciprocity between, 688.
Osmotic pressure of human bile, 672.
Osteoarthropathic lesions, etiology of, 312.
Osteoarthropathy, pulmonary, in a young child, 1037.
Osteomyelitis, 759; a case of acute, 440; chronic recurrent, 591; from slight cause, followed by sepsis, 93; multiple, 759.
Osteosarcoma of orbit treated successfully by the Röntgen rays, 553.
Otitis media, bacteriological examinations in acute suppurative, 520; insidiosa (sclerosis), 439; in tuberculosis, 974; purulenta neonatorum et infantum, 118; purulent treatment of, 144, 953.
Ovarian cyst in a small girl of eight years; recovery, 591; fibroma, removal of, from an aged woman, 189; transplantation, 139; tumor, suppression of urine in, 310.
Ovariotomy during pregnancy, 590.
Ovary, conservative surgery of the sclerotic, 837.
Oxaluria, significance of, 277, 588.
Oxygen, analgesia by, 879; and muscle metabolism, 479.
Oysters, typhoid fever spread by, 102, 106.

P

Pachymeningitis, 593.
Paget's disease of the nipple, *x*-ray teatment of, 1029.
Pain, abdominal, in pleurisy and pneumonia, 883; use of alkalies for the relief of, 269.
Palate, modern surgery of congenital cleft, 884.
Palsy, the operative treatment of chronic facial, of peripheral origin, 818.
Panama Canal, medical problems of the, 97, 580.
Pan-American Medical Congress, fourth, the, 704.
Pancreas, accessory, 670; diseases of the, 673, 821.
Pancreatitis, acute, 59; chronic, 74, 348, 751; relation of cholelithiasis to acute, 678, 817; typhoid, 993.
Paracolon infection, 271.
Paraffin injection for deformity, 214, 439, 553, 840, 841, 1026.
Paralysis, brachial, post narcotic, 786; case of blower's, 429; case of pseudobulbar, due to a unilateral cerebellar lesion in a child of five years, 429.
Paralysis, facial, following middle-ear suppuration, 393; general, bacterial origin of, 981; general, curability of, by intense mercurial treatment, 110; general, following a head injury, 349; general, lumbar puncture in the diagnosis of, 56; of the circumflex long thoracic and suprascapular nerves, traumatic, 877; postdiphtheritic, 308; treatment of infantile spastic, 789.
Parasites, animal, sometimes found in man, 472; intestinal, 757.
Parasitic diseases and predisposition, 814.
Parasyphilitic affections, 110, 1031.

Para-urethral abscess, trikresolin, 669.
Paresis, acute, 456.
Paris, instruction in tropical diseases in, 583; letters from, 24, 185, 344, 385, 625.
Parliament, insanitary condition of the British houses of, 501.
Paronychia, or "run-around," an operation for, 629.
Parotid gland, tuberculosis of the, 230, 270.
Paratoditis, report of a case of epidemic, with fatal termination, 508.
Pars mastoidea, the indications for opening, 413.
Patella, operative treatment of fracture of the, 549.
Patent medicines, legislation regarding, 379.
Pathology, methods of instruction in surgical, 876; reciprocity in, 687.
Peddlers, street, to be abolished, 544.
Pelvic disease, etiology of, 69; disease in young girls, 756; inflammation, eosinophilia in, 271; suppuration, mortality following operations for, 144; tuberculosis, 229.
Pelvis, contracted, childbirth in cases of, 391; contracted, diagnosis and treatment of, 388; pathogenesis and treatment of chronic cellular and peritoneal inflammation of the, 881.
Pencil in girl's cheek for three weeks, 428.
Pennsylvania State medical examination, 103.
Pension fund for nurses in England, 584.
Perforations, gastrointestinal, 587; intestinal in typhoid fever in children, the surgical features of, 634.
Peribronchitis, 271.
Pericardium, drainage of the, 30.
Periduodena, abscess secondary to ulcer of the duodenum, 427.
Perineal structures, the better methods for the repair of, 756.
Perineorrhaphy, immediate, 557.
Perineum, 69; operation for the repair of the, 999; treatment of injuries of the, during parturition, 74.
Periostitis complicating typhoid, 476.
Peripatetic university, 422.
Peritoneal sepsis, 1005.
Peritoneum, the toilette of the, 825; treatment of the, in spreading and diffuse peritonitis, 827
Peritonitis following measles, 256; in typhoid fever without perfora-

tion, 750; peribiliary, 30; rare forms of chronic, 468; sequels of non-surgical treatment of, 75; spontaneous recovery from tuberculous, 269; traumatic tuberculous, with appendicitis.868; treatment of tuberculous, 75; tuberculous, 109, 191, 340, 431, 671, 798, 819; value of enterostomy in, 760.
Permanganate of potassium in the treatment of menstrual suffering, 576.
Pernicious anæmia following thyroid enlargement, 671.
Pertussis, a study of fifty-five fatal cases of, 309; peripheral neuritis complicating, 109; treatment of, 1030; unusual cerebral symptoms in, 1030.
Phagocytes, endothelial, of the tonsillar ring, 439.
Pharyngitis, appendicitis associated with, 350.
Pharynx, hypertrophy of the lymphoid ring of the, 88.
Phenylhydrazin sugar test, 787.
Philadelphia Academy of Surgery, 863.
Philadelphia, College of Physicians of, 422, 582, 782; section on general medicine, 463, 783.
Philadelphia County Medical Society, 64, 140, 182, 223, 303, 382, 463, 542, 623, 705, 745, 947, 986.
Philadelphia Medical Journal, sale of the, 986.
Philadelphia, department of public health and charities, 623.
Philadelphia Neurological Society, 64, 263, 382, 542, 744.
Philadelphia Pathological Society, 103, 141, 302, 463, 517, 542, 623, 705, 947.
Philadelphia Pediatric Society, 140, 302, 463, 743, 864.
Philadelphia Society of Tropical Medicine, 504.
Philhower, George B., specific treatment of diphtheria, 491.
Philippines, effects of the climate of, upon Americans, 305; health of troops in the, 462; letters from the, 265, 305, 345, 465, 506, 546, 585, 626, 666, 706, 746, 949, 989; 1029; report of the government laboratories of the, for 1902, 702.
Phipps' tuberculosis institution, 102.
Phlebitis, septic, of the roots of the portal vein, 826; syphilitic, 386.
Phosphorus, in the treatment of rachitis, 430.
Photographing through the body, 65.
Phototherapy, 65; new lamps for, 586.
Physical education at Columbia, 423.
Physician, how to be successful as a, 861.
Physicians, duties of, to each other and to the profession at large, 792.
Physicotherapy in the treatment of fibromata and prevention of neoplasms, 881.
Physiology in the schools, 419.
Picric acid, some uses for, 390.
Piffard, Henry G., radio-praxis, 361, 392.
Pigmentations, cutaneous, of genital origin in the woman, 785.
Pill, the, and the bill, 478.
Pilocarpine in the treatment of pneumonia, 868; in the treatment of scarlet fever, 431.
Pin-worms in the appendix, 634.
Pituitary body, an experimental study of the function of the, 599; gangrenous destruction of, following a fracture of the sphenoid, 428; tumor of the, 496.
Placenta, adherent, discharged after a long process of decomposition, 898; prævia, treatment of, 587, 881, 882, 884.
Plague, bactericidal power of the serum in, 71; bacteriological diagnosis of, 79; care of laboratory, in Berlin, 945; dissemination of, 17; in various places, 63, 105, 140, 178, 181, 262, 423, 521; prophylaxis of, 797; serum treatment of, 109; sources and manner of infection of, 797; transmissibility of the, 188.
Plantar nerve, internal, multiple fibromata confined to the, 776; reflex in epilepsy, with special reference to the Babinski phenomenon, 508.
Plasmodiophora brassicæ, 198.
Pleura, rapid effusion of serum in the, 1031.
Pleurisy, abdominal pain in, 758, 883; cytodiagnosis of cancerous, 913; treatment of, in New York hospitals, 45.
Pleuritis pulsans dextra, 955.
Plugging bone cavities, 834.
Pneumonectomy, 75.
Pneumonia, abdominal pain in, 758, 883, 911; altitude in relation to, 993; antitryptic property of the blood serum in croupous, 820; autolysis in, 917; complicating typhoid, 476; ergot in, 516; gonococcal, 714; hypodermoclysis in, 268; immunity after recovery from, 787; increase of, 181; infectious nature of, 508; influence of altitude on the mortality of, 588; interstitial, in children, 271; management of catarrhal, in infants, 1030; nitrogen excretion in, 40; pilocarpine in, 868; prevention of, 256; serum treatment of, in infants, 1037; traumatic, 758; treatment, 588, 630.
Pneumococci, a convenient medium for growing and storing cultures of, 633.
Pneumonopexy, 75.
Pneumonorrhaphy, 75
Pneumonotomy, 74.
Pneumothorax, a case of, 113; method of eliciting the coin-percussion sound in, 955.
Poison oak, the active principle of, 855.
Poisoners, domestic, 639.
Poisoning, acute alcoholic, in a child aged four years; treatment by saline injection; recovery, 868; arsenical, and Hodgkin's disease, 868; by chlorate of potassium, 776; by chlorodyne, with recovery, 868.
Poisoning, by quinine, 535; structural changes which occur in experimental lead, 869.
Poliomyelitis, an epidemic of acute anterior, 656.
Political control of the State institutions, 583.
Polyarthritis in children, Still's type of, 601, 1038.
Polyhydramnios, 80.
Polypi, 555.
Poor, housing of the London, 501.
Portal anastomoses, anatomy of, 552; in cirrhosis of the liver, 336.
Posterior-occipital positions, the management of, 557.
Post-mortem examinations, medico-legal, 589.
Post-operative mortality, 834; pulmonary complications, 629.
Post-typhoid sepsis, 823.
Potassium chlorate, fatal case of poisoning by, 776.
Practitioner, change in the editorial management of the, 300.
Practitioner, examination of milk by the general, 532; laboratory diagnosis and the general, 619; the general, and his relation to early surgical operations, 883.
Practitioners' Society of New York, 113, 674, 841.
Pregnancy, abdominal, of twenty-one months duration, 911; apparent secondary abdominal, in a rabbit after primary rupture of the uterus, 511; bilateral extra-uterine, 881; complicated by myometa, 828; extrauterine, 46, 406; multiple, 267; ovariotomy, during, 590; phantom, 310; recurrent tubal, 434; thyroid extract for impending eclampsia in 605.
Prescription, pharmacological complexity in the medical, 717.
Preventive medicine, 942; Providence, R. I., 891.
Price, Marshall Langton, fatal gastric hemorrhage, with autopsy, 892.
Pritchard, William Broaddus, diagnostic and prognostic data in nervous and mental diseases, 936.
Prizes, award of, at the fourteenth international congress at Madrid, 718; Craig Colony, 223; Edward N. Gibbs, memorial, 23; Enus-Sander, 141; for essay on tropical skin diseases, 178; Samuel D. Groos, of the Philadelphia Academy of Surgery, 382; of the Paris Academy of Medicine, 344.
Profession, the duties of the, to the public, 795.
Professional services to each other, 777, 909.
Prophylaxis of venereal diseases, 425
Prostate, hypertrophy of the, 69; hypertrophy of the, ergot in, 517; hypertrophy of the prostatectomy and galvanocaustic prostatotomy, 876; surgery of the, 799.
Prostatectomy, technique of, 197; total for radical cure of enlargement of the organ, 713.
Proteids, on the biological relationship of, and on proteid assimilation, 495.
Prout, Thomas P., the problem of epilepsy, some suggestions for its solution, 252.
Prudden, T. Mitchell, a résumé of some recent researches relating to cytolysis and immunity, 241.
Pruritus vulvæ, surgical treatment of, 818.
Pseudarthrosis, treatment of, 191.
Pseudoleukæmia, infantum, demonstration of blood smears in a case of, 473; *x*-ray in treatment of, 670.
Pseudotabes, syphilitic, 587.
Psoriasis and molluscum contagiosum, the local treatment of, 671.
Psychical element in hay fever, 494.
Psychiatrical Society of N. Y., 423.
Psychopathic hospital for New York, 342.
Psychosis, the intoxication, due to iodoform, 499.
Pubes, lateral section through the, 183.
Public health, degree of doctor of, 139. law, amendments to the, 301.
Puerperal eclampsia, apomorphine for, 940; eclampsia, renal decapsulation for, 121; eclampsis, morphine in, 1031; eclampsia, surgical treatment of, 86; eclampsis treatment of, 1033; hyperpyrexia of malarial origin, 311; pyrexia, cases of non-septic, 456; sepsis, 919; sepsis, intravenous infusion in, 974; sepsis, treatment of, 557, 670, 867, 882.
Pulmonary abscess producing dextrocardia;; and case report, 671; complications, post-operative, 629; cures, warning the poor against, 543; disease and nasal diseases, relation between, 478; œdema, ergot in, 515.
Pulmonary tuberculosis, American climates in the treatment of, 194; bed-rest in the fever of, 912; complicated by tuberculous meningitis and delusional insanity, 612; curability of, 879; dietetic treatment of, 511; following thoracic

traumatism, 673; genesis of, 1021; influence of mind on, 912; meningitis as a terminal event in, 296; prognostic value of the diazo-reaction in, 588; relation of acute bronchitis to, 879; selection of cases for sanatorium treatment, 955; study of weights in pulmonary, 712; traumatism as a factor in the etiology of, 911; see also *Consumptives* and *Tuberculosis*.
Pulsus infrequens, 199; paradoxus, 954.
Purpura, angioneurotic, 669; complicating typhoid, 476; ergot in, 516; fulminans, 353; hæmorrhagica following sea bathing, 146; hæmorrhagica, hemorrhagic appendicitis as the first manifestation of, 207; rare form of, 348; rheumatic, 271.
Pyelitis complicating typhoid, 476.
Pygmies, prehistoric, 315.
Pylephlebitis, 1005.
Pylorus, congenital hypertrophic stenosis of the, 70; congenital spasm of the, 1038; neurosis of the, 229; neoplasia of the, 787; obstruction of the, 759; tetanic form of cancer of the, 913; treatment of benign stricture of the, 396, 470.
Pyosalpinx complicating pregnancy, 594; operation for, during acute gonorrhœa, 594; removal of the uterus in double, 956.

Q

Quack, an American, in Europe, 502; methods of the, 984; the, and Sabatier, 640.
Quarantine, in relation to yellow fever, 410.
Quinine and malaria, 621; and other remedies in the cure of malarial fever, the fluorescence of, 782; report of a case of almost fatal poisoning by six grains of, 535; treatment of cholera, 668.

R

Rabbit, a simple method for obtaining blood from a, 633.
Rabies, 790; etiology of, 1032; formalin injections in, 422; in the dog, the diagnosis of, 879; prevalent in New York, 623.
Radiotherapy, results in, 952; see *Röntgen*.
Radiopraxis, 361, 392.
Radium, heat from, 544.
Radius, congenital dislocation of the, 838.
Rachitis, etiology of, 1036; phosphorous in the treatment of, 430.
Railway cars, methods of cleaning, 338; employees, eye-tests for, 196.
Ranney, Ambrose L., eye-strain in youth and its modern treatment, 606.
Reciprocity, medical, in Michigan, 182.
Rectal feeding in febricula and typhoid fever, 107.
Rectal muscles, congenital, absence of both inferior, 630.
Rectum, a study of the, with reference to the causative factors of obstipation, 767; cancer of the, 72; catarrhal inflammation of the, 555; diuretic action of irrigation of the, 68; office treatment of diseases of the, 554; operative cure of prolapse of the, 896; operative treatment of carcinoma of the, 739; sigmoidoproctectomy for cancer of the, 451.
Recurrent fever, lymphadenoma associated with, 320; tubal pregnancy, 434.
Red Cross Society, trouble in the, 222, 582.
Reed, Major Walter, statue to, 815; tribute to, 791.
Refuse, utilizing city, 781.
Renal hæmaturia of six months' duration without apparent lesion, 835; lesions in infancy, synopsis on some of the, 830.
Respiration in high altitudes, anomalies of, 867.
Respiratory apparatus, sepsis of the, in early childhood, 471; failure from ether—artificial respiration for over four hours; recovery, 810; quotient as influenced by tuberculosis, 548.
Rest, value of physiological, 310.
Resuscitation, value of adrenalin in, 182.
Retinal artery, a case of endarteritis obliterans of the central, 842; hemorrhage, 348; hemorrhage, recovery from, 144; hemorrhage as a diagnostic feature in fracture of the base of the skull and in subarachnoid hemorrhage, 856.
Retinoscopy, 194.
Retraction and retractors in abdominal surgery, 677.
Retractor, automatic cœliotomy, 434.
Retrocæcal appendicitis with retroperitoneal pelvic abscess, 867.
Retroversion of the uterus, symptoms, complications and treatment, 757.
Rheumatic fever, case of, complicated by chorea, iritis, and endocarditis; recovery, 510; tonsillitis in children, 867.
Rheumatism, a case of cerebral, 673; acute and sepsis, 819; acute, the salicylates in, 480; cataphoresis in, 31; cold baths in cerebral, 80; cured by bee stings, 863; diet in, 256; embolism in acute, 1031; eye affections complicating and resulting from, 629; micrococcus of acute, 618; nature of, 879; passing of chronic, 798; salicylates in acute, 226; surgical treatment of, 269; treatment of, in New York hospitals, 44; tuberculous, 112.
Rheumatoid arthritis, a cerebrospinal toxæmia, 280; associated with Graves's disease, 818; ferrous iodide in, 216; reflexus in, 70; pathology of acute, 778; remarks on, 601.
Rhinitis, atrophic, the presence of diphtheria bacilli in, 470; hypertrophic, 568; hypertrophic, the galvanocautery in, 479.
Rhodan in the nasal secretion, 932.
Rhus diversiloba (poison oak), on the active principle of, 855.
Richardson, H., the treatment of diseases of the liver, 176.
Richmond Borough, trouble at a hospital in, 423
Ring bodies in anæmic blood, 496.
Ringworm, the treatment of, 575
Roberts, George W., sigmoidoproctectomy for cancer of the rectum, 451.
Rockefeller Institute, land for, 704; plans of the, 341.
Rockwell, A. D., the *x*-ray and the Finsen light in the treatment of lupus, 575.
Rodent ulcer, a case of, 818.
Röntgen rays, 587, 910; cancer caused by, 106, 354; diagnostic uses of, 77; gangrene caused by, 553; in cancer, 23, 68, 77, 78, 309, 441, 837, 845, 874; in cancer of the cervix, 200; in Hodgkin's disease, 341; in lupus, 575; in osteosarcoma of orbit, 553; in pseudoleucæmia, 670; in sarcoma, 450, 673, 871; in trachoma by the, 268; pathology of tissue changes caused by the, 271, 554; presence of, in the spectrum, 503; protection against dermatitis from, 164, 223; results of treatment by the, 233, 873; uses of, in anthropometrical signalment, 786.
Roof-garden dormitory, 863.
Roosa, D. B. St. John, a case of disease of the acoustic nerves, causing profound deafness, accompanied at a later stage by pleuritic effusion and fibroid phthisis—recovery, 163.
Roosevelt Hospital, 581; annual report of, 704.
Ross, John W., reasons for believing that the only way in nature for yellow-fever to be contracted by man is from the mosquito, 124, 231.
Rotation, nature of phenomena of, around and longitudinal axis in animals with ultimate lesions of the cerebellum, 430.
Round ligaments, a new method of shortening the, intraperitoneally for retroversion, 749; new method of shortening the, 76.
Runners, medical observations on long-distance, 347;
Russia, the sale of liquor in, 662.

S.

Sabatier and the quack, 640.
Saddle-nose, paraffin injection, see *Paraffin*.
Sailors at home, hospital for, 663.
Salicin, the discovery of the curative action of, 703.
Salicylates in acute rheumatism, 226, 480, 703.
Salicylic acid as a food preservative, 510, 617, 741.
Saline infusions in abdominal operation, a clinical and laboratory study of the effects of peritoneal 756; solution, in the treatment of hemorrhoids, 415; solution, possibilities of, 600; solution, value of, 120.
Salt cure for cancer, 664.
Sanatoria for consumptives, need of local, 281, 314; novel on incidents in, 344.
San Francisco, quarantine against, 461.
Sanitation, politics in relation to, 308.
Saphenous vein, ligation of the internal, 343.
Sarcoma, a case of multiple melanotic, unsuccessfully treated by *x*-rays, 673; of the antrum of Highmore; operation, 554; of the kidney treated by *x*-rays, 910; of the tibia treated by evacuations; recovery, 507; therapeutic value of the *x*-ray in, 871; toxins and *x*-rays in inoperable, 450.
Sarcomatous degeneration of myomata, 836.
Saw, an improved Gigli, 234.
Scarlet fever, antistreptococcus serum in, 29, 228, 301, 373; bacteriological studies of the skin and throat in cases of, 670; bacteriologic examination of the blood during life in, with special reference to streptococcæmia, 468; diffusibility of the virus of, 146; relapses in, 348; mastoid necrosis following, 1032; treatment of, 270.
Schleich's method of the treatment of wounds, 378.
Schools, medical inspection of, 193, 428, 944; physiology in the, 419.
Schwalbe, Carl, on the active principle of rhus diversiloba (poison oak), 855.
Sciatica, the surgical treatment of, 672.

Scientists, credentials for, 805.
Sclerodermatitis in children, 228.
Scripture, E. W., recent researches on the voice, 326.
Scurvy, infantile, 631, 916.
Sea-baths, indications and contraindications for, 869.
Seasickness, nature and treatment of, 1004.
Seaman, Louis L., the army cartridge-belt, 215.
Secretions, the significance of variations in the internal, 588.
Segregation of the insane, 783.
Semiteetotal pledge, 898.
Sepsis and acute rheumatism, 819; indications for hysterectomy in beginning acute, 882; peritoneal, 1005; post-typhoid, 823.
Septicæmia, bacteriology and serum treatment of puerperal, 55; formalin in, 137, 158, 177, 227; gonorrhœal, 876; relapsing, 336; the present treatment of puerperal, 867; two cases of diplococcal, 705.
Septic infection of nasal origin, general, 776.
Septum, treatment of abnormalities of the, 568.
Serum, antistreptococcic, and its use in malignant endocarditis, 510; antistaphylococcus, 590; antitetanic, spinal subarachnoid injections of, in tetanus, 670; cholera infantum, 553; diagnosis of tuberculosis, 866; some interesting phenomena of specific immune, 867; tetanus after injections of gelatinized, 869; therapeutic properties of milk, 878; therapy, 790; Trunecek's, and its value in disturbed cerebral functions caused by circulatory changes, with report of twelve cases, 509; tuberculosis, 461; typhoid fever, 461, 660.
Sewage pollution near New York City, 457.
Sexual disorders, functional, in the male, 197.
Shakespeare as a medical authority, 900.
Shaw, Henry Larned Keith, examination of milk by the general practitioner, 532.
Shelly, Edwin Taylor, the maternal impression superstition, 212.
Shiga's bacillus in diarrhœal diseases, 357; in dysentery near New York, 742.
Shock produced by general anæsthesia, 749; surgical, ergot in, 517.
Shoulder-joint, a case of habitual dislocation of the, 467; irreducible dislocations of the, 74.
Shultz, R. C., multiple pregnancy with a vengeance, 267; secondary eruption in measles, 951.
Sigmoid flexure, acute inflammation of the, 429.
Sigmoidoproctectomy for cancer of the rectum, 451.
Silkworm gut for sustaining sutures in fixation of the kidney, 423.
Silver sulphoichthyolate, physiological action of, 631.
Sinus thrombosis, 593.
Sinusitis, prophylaxis of, 347.
Skiagraphic errors, some common 77.
Skin conditions which modify the characters of inflammation of the, and their influence on treatment, 509; diseases of the, novelties in the physical treatment of, 786; inflammations of the, 390; lesion of the, associated with the rapid growth of long bones (les vergetures de croissance), 824.
Skin-grafting, auto-epidermic, 937.
Skull, fracture of the base of the, 1042; retinal hemorrhages as a diagnostic feature in fracture of the base of the, and in subarachnoid hemorrhage, 856; treatment of fractures of the, 838.
Skunk, erythrogenic spleen of the, 112.
Sleep, pathological, in an hysterical subject, 56, 61.
Sleeping-sickness, 299; etiology of, 659, 1022.
Smallpox among Digger Indians, 543; at Manila, 781; carbolic acid in, 389; complicated by aphasia, 789; germ, the discovery of the, 703, 981; guaiacolin, 954; guards, strike of, 782; in England, 983; in Indiana, 541; red-light treatment of, 994; school and churches closed on account of, 502; study of the contents of the vesicles and pustules of, 308; treated by serum from immunized heifers, 671; vaccination in relation to, 101.
Smiles, Dr., ninetieth birthday of, 359.
Smith, A. Alexander, some questions in heredity, 81, 114.
Smith, Stephen, how to study anatomy, 1.
Smoke nuisance, treatment of the, 99.
Sobel, Jacob, an emergency milk warmer for infants and young children, 224.
Social conditions in America in their relation to medical progress and disease, 726.
Society of College Gymnasium Directors, 63
Soil, pollution of the, 58.
Solarization of the body, 171.
Sore throat, 29.
Souchon, Edmond, maritime quarantine without detention of non-infected vessels from ports quarantined against yellow fever, 170; the explanation of the cases of yellow fever on board the S. S. Plymouth, 267.
Southern fevers, 752.
Spain, medical practice in, 262.
Spasmodic affections, on the surgical treatment of localized, 785.
Specialty, the expansion of a, 693.
Spectacles, use of, in the British army, 120.
Spectrum, *x*-rays in the, 503.
Spermaturia, 992.
Sphenoid, fracture of the, followed by gangrene of the pituitary body, 428.
Spina bifida, treatment of, 172, 496.
Spinal cocainization, 835; cocainization, theory and practice of, 201; cord, condition of the deep reflexes in transverse lesions of the, 183; cord, differential diagnosis of the familial forms of, 194; cord, histological changes in the, due to local injections of cultures of staphylococcus, 591; concussion, so-called, 549; disease mimicry of gastric troubles by, 312; lymphocytosis and ocular affections, 869.
Spinalgia as an early symptom of tuberculous infection, 511.
Spine, primary osteomyelitis of the, 912.
Spirit drinking, toxæmias from, 620.
Spitting nuisance, 300, 863.
Spleen, abscess of the, 840, 955; blood changes after extirpation of the, 787; changes in the, in cirrhosis of the liver, 229; enlarged, and chronic cyanosis, with polycythæmia: a new clinical entity, 871; hydatid cyst of the, 509; laceration of the, 776; splenopexy for wandering, 820; the relation of chronic enlargement of the, to anæmia in infancy, 870; traumatic rupture of the, 270; wandering, 862.
Splenic anæmia, notes of a case of, 712.
Splenopexy for wandering spleen, 820.
Sponge eduction, 844.
Sprains, plaster strapping for, 50.
Sprue, treatment of a formidable case of, by diet; the value of strawberries, 589.
Squires, G. W., hydrocephalus complicating labor, 775; reflex symptom from biliary calculus, 856; tumor complicating labor, 655.
Stain, a new blood, 1017; for the gonococcus, 844; for the malarial parasite, a new 819.
Staphylococcus aureus, notes on systemic infections by the, 670; infection, acute general, through the puerperal breast, 836; infection, notes on systemic, 474; infection, changes in the spinal cord due to, 591.
Stark, Henry S., the pathogenesis of diabetes, 650.
Starvation as a therapeutic agent, 800; in typhoid fever, 476.
State, compensation for medical services rendered the, 859; institutions, political control of, 583.
Statistics, Harvard, health, 461; of yellow fever, 410; vital, 813.
Steam in gynecology and general surgery, the use of, 679.
Stenson's duct, stenosis of, 232; the results of the ligature of, 591.
Sterilization of instruments, handy method of, 219.
Sterilizer and water heater, a rapid, 834.
Stern, Heinrich, a contribution to the pathogenesis of the uræmic state; the probability of its psychoelectric substratum, 121.
Sternum, removal of, and reproduction of bone, 554.
Stevens, anti-vaccinationist, death of, 663.
Stewart, Douglas H., the surgical treatment of puerperal eclampsia and the prevention of convulsions, 86.
Stomach, a personal record of the surgery of the, 872; acute dilatation of the, 189; cancer of the, difficulty in diagnosis of, 549; cancer of the, importance of early diagnosis of, with a view to radical treatment, 751; crises, 971; diagnosis of ulcer of the, 280; fatal hemorrhage from the, 892; functions of the, after splenectomy, 1032; generalized cancer of the, 430; gunshot wounds of the, 74; indications for surgical intravention in affections of the, 835; mimicry of diseases of the, by spinal troubles, 312; motor insufficiency of the, in children, 187; neurosis of the pylorus, 229; operation for chronic ulcer of the, 70; operations upon the, with special reference to the toilette of the peritoneum, 826; surgery of simple diseases of the, 952; surgery of the, 759; surgical treatment in non-malignant diseases of the; results and indications, 468; surgical treatment of hour-glass contraction of the, 834; technique of lavage of the, 240; value of examination of the contents of the, 396.
Stomatitis epidemic in South Africa during the recent war, 429; puerperal, 1032.
Stone in the kidney, the symptoms and diagnosis of, 751.
Stony Wold, the work at, 422.
Stramonium, poisoning by, 111.
Strawberries, value of, in sprue, 589.
Street, varying death rate on opposite sides of the, 187.
Street-car colds, 462; crowding in

New York, 21, 318; ventilation, 259.
Street-cleaning bill, passage of, 662.
Streptococcus and staphylococcus bronchitis, 549; in the mouths of breast-fed infants, 190; infections, 911.
Stricture, treatment of urethral, 36.
Stridor, congenital inspiratory, 991.
Stronguloides intestinalis in the U. S., the occurrence of, 757.
Strychnine, fixation of, in the animal tissues, 239.
Study, Joseph, N., bronchopneumonia, 573.
Stump, in partial hysterectomy, 881.
Subconjunctival injections, 470.
Subinvolution, postpartum, 550.
Subperiosteal abscess, of otitic origin, 593.
Subphrenic abscess complicating appendicitis, 187.
Substitution by druggists, 221, 342.
Subway locomotion, 703; ventilation of the, 663.
Sugar test, phenylhydrazin, 787.
Sulphur disinfection, in yellow fever, 412.
Summer diarrhœas of infancy, 757.
Sunshine and fresh air versus Röntgen and Finsen rays in the treatment of tuberculosis of bones and joints, 837.
Sunstroke, nature of, 310.
Suppression of urine, 753.
Surgeon's enemy, the skin, 197.
Surgery, abdominal, some of the complications of, 467; "bloodless," 421; ergot in, 515; opium in, 549.
Surgical operations, the general practitioner and his relation to early, 883; pathology, methods of instruction in; lantern-slide demonstration, 876; shock, ergot in, 517; shock, the treatment of, by adrenalin, 877; treatment of nephritis, 754.
Survivorship, doctrine of, in case of two or more deaths in a common disaster, 328.
Suspensory bandage, a new, constructed on anatomical lines, 636.
Sutro, Theodore, doctrine of survivorship in case of two or more deaths in a common disaster, 328.
Suture, removable deep, 994.
Sympathectomy for exophthalmic goiter, 875.
Sympathetic, effects of section of the cervical, 66; system, application of alternating currents to the abdominal, 953'
Symphyseotomy, condition of the pelvis after, 312.
Synechia pericardii, Talma's operation for, 1032.
Synovial ganglia, heredity of, 216.
Synovitis, septic, 146.
Syphilis, alleged bacillus of, 190; as a cause of chorea, 718; cutaneous mercurial reaction in, 390; heart affections in, 228; hereditary, the diagnosis and treatment of, 468; immunity against, 228; in the barber shop, 66; mercurial reaction peculiar to, 111; mercury in, 426, 991; open-air treatment of, 161; the inheritance of, 699; theories of the transmission of hereditary, 818; transmitted by dental forceps, 776.
Syphilitic pseudotabes, 587.
Syringomyelia, crossed adductor reflex in, 29.

T

Tabes dorsalis, astereognosis, 311; curability of, by intense mercurial treatment, 110; etiology of, 954; hereditary, 24; incipient, 350; involuntary movements in, 28; juvenile, and its relation to hereditary syphilis, 751; massage in, 66; multiple sclerosis, associated with, 712
Tachycardia, epileptic, 923; essential and paroxysmal, 204; paroxysmal, associated with epilepsy, 120.
Tachypnœmia, hysterical, with organic cardiac lesions, 429.
Telmas' operation for cirrhosis of the liver, 230.
Tea, intoxication by, 227.
Teeth as a cause of pathological conditions elsewhere, 226, 548.
Telephone, the public, as a transmitter of disease, 579.
Temperature, comparative value of the mouth, the rectum, the urine, the axilla, and the groin, for observation of the, 589; effects of low, upon organic life, 400; high, in a young infant, 120; observations as to taking, 660.
Temporal bone, operative treatment of chronic suppuration within the, 671.
Tendo Achillis shortened for the restoration of the function of the calf, lost as a result of a previous tenotomy, 748.
Tendon transplantation in infantile paralysis, 319.
Tenement-house problem, 192, 297, 377.
Tennessee State Medical Association, 705.
Tension, intracranial, indications for operative interference in, 508.
Testicle, surgery of undescended, 838; torsion of, 952.
Tetanus, a case of acute, with certain points of interest, 509; a study of 57 cases from the records of the Pennsylvania Hospital, 817; antitoxin treatment of, 550, 710; bacilli in a wound, prompt excision; no tetanus, 788; bacilli in gelatin, 420; bacilli in the blood, 551; following injections of gelatinized serum, 869; following vaccination, 110; Fourth-of-July, 993; injections of brain emulsion in traumatic, 581; lesions which favor the development of, 876.
Tetanus, pathogenesis of gastric, 430; treatment of, 16, 24, 36, 101, 670.
Tetany, complicating typhoid, 476.
Texas, climate of western, for tuberculosis, 908.
Thalamus, the plan of the construction of the, 717.
Thalassotherapy, congress of, 21.
Thermometer shield, the, 599.
Thermatoxis of the white blood-corpuscles, 496.
Therapy, local *vs.* general, 108.
Thomas, T. Gaillard, memorial address on the late, 1015.
Thomson, Arthur, cranial form in man, together with some remarks on the attitude of the profession toward anthropology, 681.
Thomson, Edgar S., the treatment of purulent conjunctivitis, 852.
Thomson, W. H., uræmia and ts treatment, 761.
Thoracic traumatism and pulmonary tuberculosis, 673.
Throat, importance of frequent cultures in diseases of the, 187.
Thrombi, free spherical, in the cavity of the heart, 520.
Thymus death in infancy, 916.
Thyroid extract in hæmophilia and other forms of hemorrhage, 427; in the treatment of the autointoxications of pregnancy; anticipation of impending eclampsia, 605.
Thyroid gland, enlargement of the, followed by pernicious anæmia, 671; experiments to determine the function of the, 388; fibroma of the, 312; pathology of the, 918.
Tibia, sarcoma of the, treated by evacuation, recovery, 507.
Tillman, Hermann, in America, 780.
Tobacco, deafness caused by, 397; effects of, on the tissues of the rabbit, 112.
Toledo Academy of Medicine, 141.
Tongue, operation for cancer of the, 349.
Tonsil, as a portal of tuberculous infection, 824.
Tonsillar ring, the endothelial phagocytes of the, 439.
Tonsilitis, acute, 111; excision of the tracts during, 189; in children, rheumatic, 867; infectious character of, 188; relation of, to appendicitis, 267.
Toxæmias from spirit drinking 620.
Toxic substances applied to the skin, effects on peripheral nerves of, 719.
Toxins, in the treatment of inoperable sarcoma, 450; intracellular, of some of the pathogenic bacteria, 549: rôle of the, in inflammation of the eye, 588.
Trachoma, 311, 315; analogy of, to, adenoids, 14; in the public schools of New York, 293, 316; in the United States and in Egypt, 620; relation of follicular conjunctivitis to, 132; *x*-ray treatment of, 268.
Traction injury of arteries, 883.
Trap-drummers' neurosis, 268.
Treatment, local, for localization of general diseases, 380; old methods of, not necessarily obsolete, 679.
Trichinosis, eosinophilia of, 919.
Tri-County Medical Society of South Jersey, 1025.
Trigenurial neuralgia complicating typhoid fever, 389.
Trional poisoning, a case of acute, 712.
Tropical diseases, instruction in Paris in, 583; dysentery, 757; fever, differentiation of, 948, 954.
Tropics, surgery in the, 190; military hygiene in the, 460.
Trunecek's serum, and its value in disturbed cerebral functions caused by circulatory changes, with report of twelve cases, 509.
Trypanoromiasis, case of, 954.
Tubercle bacillus, recognition of, in the sputum, 313.
Tuberculin test, infectiveness of milk of cows which have reacted to the, 858; uses of, 315.
Tuberculosis, 791; camp for the treatment of, in New York City, 301; campaign against, in Latin America, the, 690; combat against, 502, 504, 577, 690, 905; conjunctional, *x*-ray treatment of, 944; curability of, and sanatorium treatment, 138; diffuse, of the pelvic cellular tissues, 229; following injection of tuberculin, 913; hospital for, in New York City, 257; human and bovine, 339, 824, 904; immunization against, 309, 716, 823, 993; in the negro, 798; infection of, through the lymphoid structures of the throat, 228; infectivity of, 377; international congress on, at St. Louis, 342; laryngeal, and pregnancy, 470; lupus erythematosus in relation to, 109; lymphatic, 994; malignancy of articular, 109; mammary, 839, 924; mesenteric, leukæmia associated with, 396; New Jersey sanatorium for, 339, 582; nosography and pathogenesis of, 878; of the female genitals, 884; of the pericardium, 818; of the upper air-passages, 347;

open-air treatment of, cause of the success of, 10; osseous, treatment, 837; parotid, 230, 270; peritoneal, 109, 340, 798, 819; Phipps institution for the study of, 102; prevention of, 941; prognostic value of the diazo-reaction in, 278; prophylactic and therapeutic indications in, 718; pulmonary, see Pulmonary tuberculosis; serum diagnosis of, 866; serum treatment of, 221, 461; sanatorium treatment of, 313; spontaneous recovery from peritoneal, 269; tent for use in out-door treatment of, 393; tonsillar, 824; treatment of laryngeal, 787; treatment of cutaneous, 835; treatment of external, by heat, 834; tuberculin in the diagnosis of, 912; zomotheraphy in, 995.

Tuberculous cerebrospinal meningitis complicating pulmonary and laryngeal tuberculosis, 612; meningitis and typhoid fever, association of, 412; patient, should he know the truth regarding his condition, 799.

Tumor complicating labor, 655; danger of delay in the case of large abdominal, 864; multiple primary 68; obscure abdominal, 595; of the breast, importance of early removal of doubtful, 672; of the cæcal wall following the removal of an appendix, 803; of the larynx and velum palati, 591; of the pituitary body, 496; surgery of cerebral, 877; transplantion of, 469; treatment of vascular, by the injection of boiling water, 759; *x*-raytreatment of malignant, 441.

Turbinate body, restoration of, by paraffin injection in atrophic rhinitis, 189.

Tuthill, H. Randolph, cold and disease, 12.

Twins, duplication of fears in, 220.

Typhoid and paratyphoid injections and malignant endocarditis, resemblances of, 786.

Typhoid bacilli, free receptors of, 311.

Typhoid fever, 791; abscesses of the liver following, 861; acetozone in, 924; bilberry as a remedy for, 311; bacteriological study of the blood in, 739; blood counts in, 633; diagnosis of cholecystitis in a case of, 869; diet in, 267; dissemination of, 180; dissemination of, by infected army blankets, 863; drug treatment of, overdone, 631; early diagnosis of, by culture from fecal matter, 61; Ehrlich's test in, 993; fasting in, 753; fetal, 512; flies as carriers of, 388; grape-juice as a preventive, 182; hemorrhagic, 264; in armies in the field, 217; in children, 226, 476, 512, 634; in Cleveland, 980; in Colorado, a report of 529 cases of, 753; in Ithaca, N. Y., 262, 301, 341, 422, 583; in private practice, 267; in Stanford University, 662; Koch's views on, 497; lemon-juice as a preservative against, 21, 63, 104; modes of infection of, 795; oysters as spreaders of, 31, 60, 102, 106; perforation in, 146, 630, 749, 826; perforation in, value of blood-pressure determinations in the diagnosis of, 786; peritonitis in, without perforation, 750; prevention of, in armies, 70; prevention of, difficulties in the way of, 796; prophylactic treatment of, by inoculation, 240; psychoses of, 1003; rectal feeding in, 107; sequelæ of, 132, 420; serum treatment of, 143, 390, 461; statistics of, 477; surgical features of, 256; surgical mistakes in, 145; symposium on, 795; treatment of, 478, 787, 880; treatment of, in New York hospitals, 41; treatment of some of the surgical complications in, 670; trigeminal neuralgia complicating, 389; tuberculous meningitis associated with, 412; value of the leucocyte count in, 71; Widal's test, 844, 993.

U

Uhlenhuth test, for the differentiation of human blood, limitations of the, 467.

Ulcer, a case of rodent, 818; gastric, clinical, pathological, and surgical phases of, 755; gastric, surgery of, 751, 758, 866; gonorrhœal cutaneous, 511; perforating gastric and duodenal, 885; single, of the urinary bladder non-tuberculous and non-malignant, 827.

Ultramicroscopic organisms, 790.

Ultraviolet light, portable and easily adjusted mechanisms for, 517.

Umbilicus, secondary hemorrhage from the, 110.

Uncinariaris, 68; in the United States with especial reference to its occurrence in Texas, 757; mode of infection, 142; treatment of 757.

Unification, educational, 539.

Universities, medical supervision of, 467.

University, a peripatetic, 422.

Upper-air passages, and gastrointestinal tract, relation of the diseases of the, 676.

Uræmia and its treatment, 761; therapeutic management of, 199; tumor in relation to, 190.

Uræmic state, pathogenesis of the, 121; some points pertaining to the therapeutic management of the, 750.

Ureteral calculus of 44 grams; transperitoneal ureterolithotomy; recovery, 788.

Ureteritis, ureteroscopical diagnosis and treatment of chronic, 785.

Urethra, treatment of stricture of the, 36.

Urethral and œsophageal strictures, treatment of, by linear electrolysis, 835.

Urethritis, urethroscopical diagnosis and treatment of chronic, 1019.

Urethroscopy, guide-obturator for posterior, 1041.

Urethrovaginal fistula, treatment of, 881.

Uric acid, leucolysis in relation to the excretion of, 994; meaning of, 310.

Urinary analysis, a hint in, 900; infection, anaerobic microorganisms in, 270; pigment, estimationof the, and its diagnostic importance, 713; tract in the female, surgery of the, 839.

Urination and defecation, the psychic nature of some disturbances of the acts of, 550.

Urine, acid sodium phosphate in alkalinity of the, 985; and fæces, estimation of putrefactive products in the, by the means of Ehrlich's aldehyde reaction, 833; excretion of volatile fatty acids in the, 713; hyperacidity of the, 277; residual, 308; separation of the, of the two kidneys, 191, 1020; suppression of, 753; suppression of, in a case of ovarian tumor and pregnancy, 310.

Urotropin, toxic actions of, 960.

Uterine adnexa, conservative surgery of the, 881; fibroma, and cystic kidneys, 869.

Uterus, abdominal section for adherent retroversion of the, 1435; cancer of the, 72, 348; cancer of the cervix, 922; changes in the course of acute infectious diseases, 675; conservative surgery of the appendages of the, 1032; etiology of diseases of the, 69; fibroma of the, near the menopause, 911; hyperplasia of the, 77; in abnormal position, treatment of the adhesions, 435; management of malignant disease of the, 1030; operative treatment of rupture of the, 1041; prolapse of, cured by quinine, 349; removal of, for hemorrhage, 274; retrodeviations of the, 911; retroversion of the symptoms, complications and treatment, 757; separation of, from the two kidneys, 970; successful removal of a cystic fibromyoma of the, weighing 87 pounds, 884; surgical treatment of cancer of the, 921; treatment by anterior vaginal section of retrodisplacement of the, complicated by adhesions, 434; treatment of a mobile retroflexed, 881; treatment of fibroids of the, 268;

Uvula, pressure anæmia of the, mistaken for membrane, 308.

V

Vaccines, a lecture on therapeutic inoculations of bacterial, and their practical exploitation in the treatment of disease, 818.

Vaccination, a century of arm-to-arm, 296; at Mills' Hotel, No. 1, 863; details regarding, 195; during a menstrual period, 311; in Great Britain, 340; pupils of Catholic schools exempt from, 623; smallpox in relation to, 101; stylet for, 961; tetanus following, 110; triple, in France, 583.

Vaccine, bacterial impurities of, 904; bodies, hæmosiderin in, 355.

Vaccinium myrtillus in typhoid fever, 311.

Vagina, incomplete occlusion of the, 195, 427.

Vaginal douche, death from a single, 629; exploratory puncture and cœliotomy in doubtful diagnosis of diseases of female genital organs, advisability of, 837; hysterectomy of gravid uterus with carcinoma of cervix, 434; wall, prolapse of the posterior, 747.

Vaginismus, resection of the pudic nerve for, 937.

Valentine, Ferd. C., a guide-obturator for posterior urethroscopy, 1041.

Varicocele, the electrothermic angiotribe in lieu of ligatures for, 550.

Varicose veins, a coring instrument for operating on, 353.

Varix of the inferior mesenteric vein complicated by chronic ulcerated colitis, 838.

Vascular tumors, treatment of, by injection of boiling water, 759.

Vasomotor nerves, 238.

Vaughan, Harry, the thermometer shield, 599.

Veeder, M. A., why the open-air treatment of consumption succeeds, 10

Velum palati and larynx, tumors of the, 591.

Venæ cavæ, fibrous obstruction of both superior and inferior, 806.

Venereal diseases, prophylaxis of, 425, 792; patients, instruction for, 400; peril of the boy, 752.

Venesection, cases treated by, 853;

uses and abuses of, in the practice of medicine, 952.
Venous hum, a preliminary report on the, in relation to the state of the blood, 508.
Ventrofixation, the disadvantages of, 656.
Veratrum viride, antitoxic action of, 109.
Vermiform appendix, see *Appendix*.
Vertigo, aural, 388; malarial, 267.
Vessels, mosquitos on, 582.
Vincent's tonsillar ulcer, 117.
Vineberg, Hiram N., clinical notes on a series of nine consecutive cases of ectopic gestation, 406.
Vision, brain, 423; the loss of mental, 495.
Vital statistics, 813.
Voice, recent researches on the, 326.
Volvulus of the small intestine, 70; of the sigmoid flexure, 1031.
Vomiting, cyclic, in children, 30, 548.
Vulva, primary cancer of the, 922.
Vulvovaginitis in children, 401.

W

Waitzfelder, Edward, intravenous infusion in puerperal septicæmia, 974.
Wallace, Raymond, the psychical element in hay-fever, 494.
Washington, Eye, Ear, Nose, and Throat Society of, 986; insanitary condition of, 782.
Water pressure in an early case of intussusception, 479.
Watercress and cancer, 138.
Weights in pulmonary tuberculosis, a study of, 712.
Weil's disease, case of bacteriuria resembling, 952.
Weir, Robert F., some unusual cases of appendicitis, 801.
Western Surgical and Gynecological Society, 72.
West Virginia State Medical Association, 705, 947.
White, Charles S., remarks on bacteriology and serum treatment of puerperal septicæmia, with an illustrative case, 55.
Whitman, Royal, a report of final results in two cases of polyarthritis in children of the type first described by Still, together with remarks on rheumatoid arthritis, 601.
Whooping-cough, treatment of the paroxysms of, by pulling the lower jaw downward and forward, 636.
Widal reaction in abscess of the liver, 714; in typhoid fever in children, 513; in typhoid fever, on a new method for the application of, 844.
Wilkinson, C. H., the adaptability of western Texas climate for the treatment of consumptives, 908.
Williams, Edward H., heavy medical books, 991.
Williams, Wm., the immigration bill and false medical certification, 25.
Winters, Joseph E., feeding in early infancy; home modification of milk, 366.
Woman scientist, award to, 703.
Women as army nurses, 98.
Worm, coughed up by man, 663.
Wound, blank cartridge, infected with tetanus bacilli; prompt excision, no tetanus, 788.
Wounds, Schleich's method of the treatment of, 378; the closure of, 839.
Writing, cortical center for, 193.
Wyman, Walter, organization of the Bureau of Public Health and Marine-Hospital Service, 933.

X

X-rays, see *Röntgen rays*.

Y

Yersin' serum in the treatment of bubonic plague, 819.
Yellow fever, alleged parasite of, 25.
Yellow fever and malaria, 500, 791; and the Panama Canal, 580; epidemics of, 411; in Cuba, 704; methods of quarantine against, in Havana, 83; mosquitos as the sole carriers of, 124, 231, 410, 950; on the *S. S. Plymouth*, 267; quarantine against, 170; symposium on, 796; the mode of transmission of, 796.

Z

Zurich, letters from, 505.
